INDEX TO VOLUME CXXIX.

Abdominal Surgery. Abdominal hysterectomy for fibroids, with cases, Elliot, J. W., 57, 70; cases of removal of the appendix vermiformis between attacks of relapsing inflammation, Cabot, A. T., 89; a useful method of drainage in supra-pubic cystotomy, Cobb, F., 197; appendicitis from the point of view of the physician, Eliot, G., 269; the operative treatment of peritoneal tuberculosis, Conitzer, 282; hysterectomy for cancer of the cervix by continued abdominal and vaginal dissection, Richardson, M. H., 436, 444; intraperitoneal cystotomy, Harrington, F. B., 443; some abdominal operations, Richardson, M. H., 491; discussion on the treatment of appendicitis, Dennis, F. S., and others, 497; some cases of laparotomy, Haven, G., 541.

Abortion. A case of criminal abortion, Draper, F. W., 121.

Acquaintance, "The new acquaintance," 258.

Adams, Z. B. Apparatus for fracture of the humerus through or near the deltoid insertion, 198.

Addison's Disease. A study of Addison's disease and of the adrenals, Thompson, W. G., 171.

Alcohol. The therapeutic value of alcohol in pneumonia, 99; treatment of alcoholism by large doses of strychnia, 204; a case of sudden death in an inebriate, Hurd, E. P., 593.

Aldrich, W. H. Sequelæ of la grippe, 352.

Anick Cure. Dr. Reeves and the Anick cure, 428.

Anæmia. The causation of anæmia by uric acid, Haig, 76.

Anæsthesia. Anæsthetics at the London Hospitals, 203; a statement of some of the facts in regard to the origin of the practical application of anæsthesia in surgery, Williams, J. H., 383.

Anatomy. The need of agreement on the limits of the abdominal regions and a proposition for a new method of division, Gerrish, F. H., 10, 16; the association of American anatomists, 16; delineation of abdominal regions, Balloch, E. A., 16; an anomalous external iliac artery, autopsy report, Thorndike, P., 348, 351; recent progress in anatomy, Dwight, T., 539.

Annus Medicus, MDCCCXCIII, 653.

Anthrax faciei, Wyman, S. E., 413, 429.

Anthropometry. Anthropometrical descriptions, Bertillon, 452.

Apache. The vital statistics of an Apache Indian community, Borden, W. C., 5.

Aphasia. The localizing value of aphasia, Preston, G. W., 447.

Appendicitis. Discussion in Maine Medical Association, 43; cases of removal of the appendix vermiformis between attacks of relapsing inflammation, Cabot, A. T., 89; a possible cause for the presence of appendicitis, Crehore, C. F., 151; appendicitis from the point of view of the physician, Eliot, G., 269; salines in appendicitis, 331; the use of salines in appendicitis, Richardson, M. H., 335; appendicitis, Sanborn, G. H., 353; discussion on the treatment of appendicitis, Dennis, F. S., and others, 497; appendicitis, Worcester, A., 506, 535; the relation of the bacterium commune coli to appendicitis, Fowler, G. R., 549; salines in appendicitis, Gordon, S. C., 557.

Army. Improvements in the medical department of the army, 22.

Axtell. Carcinoma of the œsophagus, 230.

Ayres, D. The male catheter, with some observations upon the proper mode of introduction into the bladder, 498.

Bacteriology. The bacteriology of suppurative meningitis, Zorkendorfer, 51; phagocytosis, Ernst, H. C., 85, 96, 114; the bacteriology of human milk, 101; bacterial poisons, 146; the bacillus pyocyaneus pericarditidis, Ernst, H. C., 252; the bacteriology of diphtheria, 379.

Bagdad pharmacy, 358.

Baker, D. E. A case of extra-uterine pregnancy, 35.

Baker, L. W. A few cases of mild mental disturbance, 537.

Baker, S. Heterogenous personality, 399.

Balloch, E. A. Delineation of abdominal regions, 16.

Barney, C. N. Staining bacteria upon the slide without using a cover-glass, 579.

Bassford, S. J. Aids to success in medicine, 44.

Bates. The hypodermic use of nitro-glycerine in epileptic convulsions, 206.

Baths. Hot baths in Japan, 630.

Baumgarten, G. On a simple continued fever, 199.

Bernhardt. A case of bilateral brachial paralysis, 230.

Bertillon. Anthropometrical descriptions, 452.

Bibliography. Aitchison, R. S., a medical handbook for the use of practitioners and students, 146; Allen, Harte, Harlan and Van Harlingen, a handbook of local therapeutics, 122; Allen, S. A., the mastoid operation, 572; Anderson, W., Heath's practical anatomy, a manual of dissections, 572; Baker, W. M., and Harris, V. D., Kirke's hand-book of physiology, 122; Balch, L., a manual for Boards of Health and Health Officers, 473; Ballantyne, J. W., and Williams, J. D., the structures in the mesosalpinx: their normal and pathological anatomy, 45; Bartholow, R., cholera, its causes, symptoms, pathology and treatment, 379; Bastian, H. C., various forms of hysterical or functional paralysis, 401; Billings, J. S., ventilation and heating, 45; Boston City Hospital, annual report, 174; Browne, L., the throat and nose and their diseases, 425; Charaka-Samhita, 333; Credé and Leopold, G., the obstetric examination, a short guide for physicians, students of medicine, midwives and students in midwifery, 121; Currier, C. G., outlines of practical hygiene, adapted to American conditions, 571; Davis, J. R. A., an elementary text-book of biology, 572; De Sinety, treatment of sterility in the woman, 571; Dibble, F. L., vagaries of sanitary science, 73; Doyen, E., traitment chirurgical des affections inflammatoires et neoplastiques de l'uterus et de ses annexes; hysterectomie abdominale et vaginale; la castration totale par le vagin, 45; Field, G. P., a manual of diseases of the ear, 571; Flückiger, F. A., reactions, 602; Graham, D., recent developments in massage, 449; Gray, L. C., a treatise on nervous and mental diseases for students and practitioners of medicine, 544; Gould, G. M., the meaning and the method of life, a search for religion in biology, 571; Hampton, J. A., nursing, its principles and practice, 305; Hartmann, J., the creation of God, 305; Hayems, G., leçons de thérapeutique, 473; Hirst, B. C., human monstrosities, 18; Howkins, J. A., a physician's pocket chart-book, 449; Inebriety, the disease of inebriety from alcohol, opium and other narcotic drugs, its etiology, pathology, treatment and medico-legal relations, 254; International medical annual and practitioner's index, 377; Jewett, Charles, outlines of obstetrics, 652; Kelynack, T. N., a contribution to the pathology of the vermiform appendix, 473; Kleen, E., hand-book of massage, 253; Lea, A. S., the chemical basis of the animal body, an appendix to Foster's text-book of physiology, 304; Leonard, C. H., the physician's pocket day-book, 522; Lepage, fonctionnement de la maison d'accouchements baudelocque, clinique de la faculté, dirigée par le Prof. A. Pinard, 304; Loomis, A., lessons in physical diagnosis, 225; Lourneau, E., chirurgie des voies urinaires, 627; Mann, J. D., forensic medicine and toxicology, 303; Marcy, H. O., the anatomy and surgical treatment of hernia, 224; Marine Hospital Service, annual report, 402; Massachusetts State Board of Health, annual report, 573; Medical News visiting list for 1894, 545; Minnesota, third biennial report of vital statistics for the years 1890, 1891, 45; Mueller, A., on snake poison, its action and its antidote, 45; Pepper, W., a text-book of the theory and practice of medicine, 202; Piersol, G. A., text-book of normal histology, 572; Playfair, W. S., a treatise on the science and practice of midwifery, 545; Ramon y Cajal, S., nouvo concepto de la histologia de los centros nerviosos, 329; Richardson, A., the law of cremation, an outline of the law relating to cremation, ancient and modern, 425; Roberts, W., on the chemistry and therapeutics of uric acid, gravel and gout, 620; Robinson, W. F., electro-therapeutics of neurasthenia, 202; Rotunda Hospital report, 229; Schaeffer, O., medical pocket-atlases, obstetrics, Part I labor, 304, Schofield, A. T., elementary physiology for students, 202; Shoemaker, J. V., a practical treatise on materia medica and therapeutics with especial reference to the clinical application of drugs, 522; Simon, W., manual of chemistry, 401; Smith, A. J., and Davis, J. A., Napheys's modern therapeutics, medical and surgical, including the diseases of women and children, 602; Starling, E. H., elements of human physiology, 304; Starr, M. A., brain surgery, 521; Stockwell, G. A., cholera, its proper aspects and its management, 279; Strümpell, A., a text-book of medicine for students and practitioners, 449; Sykes, J. F. J., public health problems, 73; Talamon, Charles, appendicitis and perityphlitis, 425; Tuttle, A. H., the surgery and surgical anatomy of the ear, 545; Van Valsat, W. W., the chronic disorders of the digestive tube, 377; Wiedersheim, R., der bau des menschen als zeugniss für seine vergangenheit, 572; Willoughby, E. F., hand-book of public health and demography, 571; Wolffhügel, zur lehre vom luftwechsel, 571; Year-book of treatment, 146.

Bier. Ligature of the internal iliac artery for prostatic enlargement, 358.

Biography. Beard, F. C., 232; Bigelow, G. T., 180; Billings, L. F., 629; Blanche, A., 232; Bodge, J. H., 432; Branham, J. W., 232; Carriere, J., 128; Carter, C. F., 528; Charcot, J. M., 206, 208, 255, 259, 600; Clark, Andrew, 427, 500, 550; Coe, A. S., 432; Colt, E., 312; Cooper, H. C., 152; Dill, R. F., 152; Dupuis, T. R., 24; Durham, A., 229; Earles, C. W., 528; Fisher, C. H., 432; Fogg, D. S., 260, 358; Fordyce, B. A., 52; Frissell, J., 528; Gould, A. K., 284; Greely, A.

J., 260; Harlan, D., 104; Hewitt, W. M. G., 284; Hoffman, P., 605; Holmes, H., 528; Horr, O. A., 44; How, L. B., 312; Hunt, E. K., 501; Jenks, W. F., 258; Jones, C. M., 451; Lailler, 309; Lane, F., 180; Latimer, J. A., 180; Levich, J. J., 80; Logan, S. M., 580; Lyman, J. B., 24; Millard, H. B., 312; Miller, S. J. F., 208; Mitchell, J. D., 80; Moncrieff, D. S., 500; Mumford, S. E., 180; Olivieri, 427; Page, H. N., 336; Parke, T. H., 334, 336; Parsons, C. W., 284; Pinneo, T. S., 208; Rae, J., 128; Renton, J., 632; Rogers, S., 206; Salter, R. H., 152; Shea, A. F., 104; Sherman, T. F., 359, 360; Sourberbielle, 577; Stebbins, W. G., 282, 404, 428; Spencer, H. W., 630; Strong, C. P., 120, 169; Thwing, E. P., 52; Towles, W. B., 336; Tyndall, J., 575; Vought, W., 336; Wardwell, W. T. S., 24; Warren, E. Bey, 312; Wheeler, E. G., 632; White, W. T., 312; Wielobycki, S., 336.

Blake, C. J. Recent progress in otology, 511.

Blake, J. G. Gastric ulcer, 542.

Blodgett, A. N. Hallux valgus, 579.

Bokenham, T. J. The proteid poison of scarlet fever, 334.

Boland, E. S. Simultaneous fracture (interarticular) of both olecranon processes, 347, 349.

Bond, C. S. Probable origin and early symptoms of certain chronic diseases of the kidneys, 171.

Borden, W. C. The vital statistics of an Apache Indian community, 5.

Boston. Typhoid fever in Boston, McCollom, J. H., 295, 300; the sanitary condition of Boston, Durgin, S. H., 298, 300.

Bowen, J. T. Report on dermatology, 274, 325.

Breast. A case of diffuse hypertrophy of the breasts, Warren, J. C., 120.

Bronchitis. Pathogeny of bronchitis, 522.

Bull, C. S. Gouty retinitis, choro-retinitis and neuro-retinitis, 519.

Burns. Cause of death in burns, Hock, 22.

Burrell, H. L. Gun-shot wounds of the joints, 369.

Burrell, H. L., and Cushing, H. W. Recent progress in surgery, 466, 493.

Cabot, A. T. Cases of removal of the appendix vermiformis between attacks of relapsing inflammation, 89; a case of calculous pyelitis with complete suppression of urine for seven days; relieved by operation, 213.

Cabot, R. C. Leukocytosis as an element in the prognosis of pneumonia, 117.

Cancer. A foreign body mistaken for cancer, Frarier, 77; the direction of cancer treatment, Snow, H., 78; on the contagiousness and inoculability of cancer, 175; erysipelas and cancer, 177.

Cannabis Indica, Edes, R. T., 273.

Catalepsy. Local catalepsy, Mitchell, 206.

Cattell. The progress of psychology, 405.

Cerebellum. Abscess in the cerebellum, Kenefick, T. A., 144.

Charaka-Samhita, 303.

Charcot, Jean Martin, 255.

Charcot. Early nocturnal pain in syphilitic spinal disease, 309.

Charite. Boycotting the Charité, 607.

Cheever, D. W. Lectures on surgery, 1, 105, 129, 153, 209, 233, 313, 361, 409, 481, 529, 581, 633.

Chemistry. Recent progress in medical chemistry, Hills, W. B., 13; physiological chemistry as a part of medical education, 426.

Chest. An extensive injury of the chest, Howe, O. T., 441.

Chicago. Letters from Chicago, 429, 453.

Children. Infantile diabetes, 51; infantile insurance, 355; the general principles underlying all good methods of infant feeding, Roteh, T. M., 505; the importance of early attention to the disability caused by infantile paralysis, Judson, A. B., 614; report on the diseases of children, Rotch, T. M., 619.

China. Letter from China, Stephenson, F. B., 311.

Chloralose. Further experience in the use of chloralose, Morrill, F. G., 422.

Chlorosis. The intestinal origin of chlorosis, Forchheimer, F., 200.

Cholecystotomy, followed by cholecystenterostomy, Hurd, E. P., 392.

Cholera. Water filtration and cholera, 74; the cholera, 124.

Chorea. Experimental observations concerning the nature of chorea, Wood, H. C., 200; the microbic origin of chorea, Dana, C. L., 448.

Circulatory System. Heart-disease or kidney-disease, Tyson, 76; recent progress in thoracic disease, Sears, G. G., 229, 250; gonorrhœal myocarditis, Councilman, W. T., 252; variations in intensity and rhythm of the cardiac pulsations, 280; an anomalous external iliac artery, autopsy report, Thorndike, P., 349, 351; ligature of the internal iliac artery for prostatic enlargement, Bier, 358; sudden death due to the heart, Councilman, W. T., 457, 472; large doses of strychnine in pulmonary and cardiac diseases, Mays, T. J., 477; fragmentatio cordis, Oestreich, 577.

Cleveland, G. Address before Pan-American Medical Congress, 277.

Climate. Climate of Colorado, Williams, C. T., 576; remarks on sending patients away from home, Knight, F. I., 609, 623.

Cloud, J. H. A case of chronic tetanus followed by scarlet fever, 395.

Clouston. The mental symptoms of myxœdema, 310.

Cobb, F. A useful method of drainage in supra-pubic cystotomy, 197; the subcutaneous injection of salt solution a substitute for the intravenous method; report of cases and a simple apparatus, 325.

Cobb, F. C. A case of angioma of the nasal septum, 510.

Cocaine, Dodge, H., 354.

Code of ethics, Hart, 357.

Coggin, D. Green's operation for entropium, 23; hinc illæ lachrymæ, 465.

Coley, W. B. The treatment of malignant tumors by inoculation of erysipelas, 22.

Collins, J. A consideration of the paræsthetic neurosis, 264.

Colorado. Climate of Colorado, Williams, C. T., 576.

Conitzer. The operative treatment of peritoneal tuberculosis, 282.

Contagion. Extinction of contagious diseases, Wyman, W., 17; on the contagiousness and inoculability of cancer, 175.

Coolidge, A., Jr. Recent progress in laryngology, 562.

Cortial. Indigestion simulating cerebral lesions, 102.

Coues, W. P. Mastoid measurements, 299.

Councilman, W. T. Exhibition of pathological specimens, 41; gonorrhœal myocarditis, 252; sudden death due to the heart, 457, 472.

Country Doctor. Work required of the country doctor, Tuell, J. E., 44.

Craigin, G. A. A case of pregnancy complicated by pneumohia and empyæma, 270, 276.

Creasote in the treatment of tuberculosis, Whittaker, J. T., 199.

Crehore, C. F. A possible cause for the present prevalence of appendicitis, 151.

Cremation. The hygienic argument for cremation considered from a bacteriological standpoint, Stone, A. K., 433, 462.

Cretinism. Sporadic cretinism in the United States, Osler, W., 252.

Croston, J. F., and Clarke, M. D. A Cæsarean section for twin monstrosity, recovery, 610.

Culkin, J. R. Mechanical violence in the treatment of diphtheria, 502.

Cunningham, T. E. Puerperal eclampsia, 416, 421.

Cutaneous System. Dermal medication, Pudor, C. A., 42; report on dermatology, Bowen, J. T., 274, 325; the increasing prevalence of the itch, Stelwagon, 406; the treatment of epithelioma and the chancroid ulcers by topical applications, North, N. J., 469.

Cutler, E. R. Sectarianism in medicine, 158, 181.

Dana, C. L. Acromegaly, gigantism and facial hemihypertrophy, 423; the microbic origin of chores, with a case, 448.

Dana, I. T. The sequelæ of pneumonia, 43.

Dandridge, N. X. The surgical treatment of pulmonary cavities, 469.

Davenport, B. F. Recent progress in foods, drugs and articles of domestic use, 93.

Davenport, F. H. Report of progress in gynecology, 441.

Deafness, congenital, 450.

Death. Legislation relating to medical matters in Massachusetts, 174; improvements in the registration of the causes of death, 306; sudden death due to the heart, Councilman, W. T., 457, 472.

De Blois, T. A. Reducing the tonsils, 375, 376.

Deitrich. Lookout Mountain as a health resort, 452.

Dentistry. Discussion of the treatment of appendicitis, 497.

Dentistry. International dental congress, 282; the medical aspect of diseased teeth, 406.

Derby, H. On certain dangers attending the use of atropine, and the employment of a new mydriatic, 640.

Dercum, F. X. Optic neuritis, blindness, deafness and the knee-jerk, cerebellar disease, 422.

Dexter, F. An intestinal anomaly, 479.

Diabetes. Diabetes mellitus, Hersom, J. L., 42; infantile diabetes, 51; diet in glycosuria, 126; jambul in diabetes, Graeser, 549.

Digestive System. The need of agreement on the limits of the abdominal regions and a proposition for a new method of division, Gerrish, F. H., 10, 16; delineation of abdominal regions, Balloch, E. A., 16; discussion on appendicitis in Maine Medical Association, 43; how should the general practitioner deal with strangulated hernia? Gerster, A. G., 61, 66; lavage of the stomach, Pick, 77; indigestion simulating cerebral lesion, Cortial, 102; visceral phlebotomy, Jaccoud, 127; gastro-intestinal exhaustion, 150; a possible cause for the present prevalence of appendicitis, Crehore, C. F., 151; subphrenic abscess, with special reference to those cases which simulate pyo-pneumothorax, Mason, A. L., 186, 201, 217, 247; relation of dyspepsia to pulmonary tuberculosis, 228; appendicitis from the point of view of the physician, Eliot, G., 269; jaundice from mental emotion, 330; salines in appendicitis, 331; the use of salines in appendicitis, Richardson, M. H., 335; appendicitis, Sanborn, G. H., 353; cholecystotomy followed by cholecystenterostomy, Hurd, E. P., 392; fermentative dyspepsia, Flint, A., 471; an intestinal anomaly, Dexter, F., 479; gastric ulcer, Blake, J. G., 542; the action of the bacterium commune coli to appendicitis, Fowler, G. B., 549; a case of dysphagia with dilatation of the œsophagus and pneumatosis, Liebman, G., 559; removal of four inches of the rectum for cancer, anastomosis by means of the Murphy button, Marcy, H. O., 561; long-continued rectal alimentation, Maragliano, 576; œsophagotomy, with healing by first intention, Post, A., 642, 650.

Diller, T. The symptoms of senility in paralysis agitans, 558.

Diphtheria. The bacteriology of diphtheria, 379; differential diagnosis of diphtheria, Ernst, H. C., 455; diphtheria, tracheotomy, persistent and increasing dyspnœa, systematic curetting of the trachea, recovery, Boudler, C. L., 465; bacteriological diagnosis of diphtheria, 476; mechanical violence in the treatment of diphtheria, Culkin, J. W., 502.

Dislocation. Dislocation of the shoulder, Thomas, 102; a new method for the reduction of dislocation of the cervical vertebræ, Walton, G. L., 423; reduction of cervical dislocation; a successful case, Walton, G. L., 553.

Dispensary. Boston Dispensary, 382.

Dodge, H. Cocaine, 354.

Dolan. Rights and duties of medical examiners in the investigation of certain cases of homicide, 472.

Donovan, J. A. Septic poisoning, a fatal case, 44.

Draper, F. W. A case of criminal abortion, 121.

Drugs. Recent progress in foods, drugs and articles of domestic use, Davenport, B. F., 93; the misuse of drugs in modern practice, Nichols, J. T. G., 239, 261, 292; "the misuse of drugs in modern practice," Johnson & Johnson, 438.

Durgin, S. H. The sanitary condition of Boston, 298, 300.

Dwight, T. Recent progress in anatomy, 539.

Ear. Mastoid measurements, Coues, W. P., 299; congenital deafness, 450; recent progress in otology, Blake, C. J., 511; further observations on removal of the stapes, Jack, F. L., 590.

Edes, R. T. Cannabis indica, 273.

Editorials. Organic extracts; the new departure in neurological therapeutics, 19; Ehrlich's urine test for typhoid fever, 46; the certification of registering thermometers, 46; the United States mail a partner of evil quacks, 47; consanguineous marriages, 74; water filtration and cholera, 74; medical exhibits at the World's Fair, 98; the therapeutic value of alcohol in pneumonia, 99; causes of longevity, 122; the milk-supply of Boston, 123; the cholera, 124; bacterial poisons, 146; the only original Jacobs, 147; postponement of the International Medical Congress, 148; legislation relating to medical matters in Massachusetts, 174; annual report of the Bos-

ton City Hospital, 174; on the contagiousness and inoculability of cancer, 175; the Pan-American Medical Congress, 202; anæsthetics at the London hospitals, 203; treatment of alcoholism by large doses of strychnia, 204; the mutual interest of the medical profession and insurance companies in the prolongation of life, 225; relation of dyspepsia to pulmonary tuberculosis, 228; Texas cattle fever and the mode of its transmission, 254; Jean Martin Charcot, 255; the tenement-houses of Boston, 256; auto-intoxications in mental diseases, 279; variations in intensity and rhythm of the cardiac pulsations, 280; improvements in the registration of causes of death, 306; the Pharmacopœia of 1890, 307; misdirected satire, 308; registration of the still-born, 330; jaundice from mental emotion, 330; salines in appendicitis, 331; twenty-first annual report of the local government board 1891-92; supplement containing the report of the medical officer, 355; infantile insurance, 355; "medical education in America," 378; the bacteriology of diphtheria, 379; "greater love hath no man than this," 402; annual report of the marine-hospital service, 402; action of iodoform on pus microbes and on the leucocytes, 403; physiological chemistry as a part of medical education, 426; may typhoid fever arise *de novo*? 426; serotherapy, 449; congenital deafness, 450; the good fortune of the Massachusetts Medical Benevolent Society, 450; the water-supply of London, 452, 474; bacteriological diagnosis of diphtheria, 476; the late Sir Andrew Clark, 499; vertical handwriting, 500; pathogeny of bronchitis, 522; epidemic influenza, 524; foot-ball, 524; a temperate word for foot-ball, 546; enteric fever in the Tees Valley, 546; the twenty-fourth annual report of the Massachusetts State Board of Health for the year 1892, 573; prevention of tuberculosis, 574; epidemic influenza, 603; the administration of hospitals for the insane in New York, 603; the pathogeny of bronchitis, 627; Annus Medicus, MDCCCXCIII, 653.

Education. Improvements in the medical department of the army, 22; the value of reading as a source of professional information, Mitchell, A., 43; the relation of hospitals to medical education, Hurd, H. M., 141; medical education in the United States, Warren, J. C., 285; "medical education in America," 378; physiological chemistry as a part of medical education, 426; the results of too many medical schools, Pepper, W., 501; report of the committee on the Harvard Medical School, 514; medical teaching in Germany, Withington, C. F., 585, 596.

Eliot, G. Appendicitis from the point of view of the physician, 269; the treatment of enteric fever, 497.

Elliot, J. W. Abdominal hysterectomy for fibroids, with cases, 57, 70.

Epidemic influenza, 524.

Epilepsy. The hypodermic use of nitro-glycerine in epileptic convulsions, Bates, 206; late epilepsy, 578.

Ernst, H. C. Phagocytosis, 85, 96, 114; the bacillus pyocyaneus pericarditidis, 252; differential diagnosis of diphtheria, 455.

Erysipelas. A consideration of erysipelas occurring during the puerperium, Galloupe, C. W., 166; erysipelas and cancer, 177.

Experts. Medical witnesses and expert testimony, Hammond, 49.

Extra-Uterine Pregnancy. A case of extra-uterine pregnancy, Baker, D. E., 35; cases of extra-uterine pregnancy, Townsend, C. W., 438, 444.

Eye. Green's operation for entropium, Coggin, D., 23; lymphoma of the conjunctiva, Goldziehei, 50; cryptophthalmus, Fuchs, 50; legislation for the prevention of blindness from ophthalmia neonatorum, 258; the eye symptoms of cerebro-spinal meningitis, Randolph, 333; atrophy of the optic nerve following iodoform poisoning, Vaiude, 405; fine lilæ lachryme, Coggin, D., 465; the relation of the patellar-tendon reflex to some of the ocular reflexes found in general paralysis of the insane, Harlan, G. C., 517; clinical history of a case of spindle-celled sarcoma of the choroid with a study of the microscopic condition of the growth, Oliver, C. A., 518; sarcoma of the choroid, sarcoma of the eyelid, Gruening, E., 518; tumor of the iris, probably tubercular, Harlan, G. C., 518; reflections upon a disastrous case of ophthalmia neonatorum, Randall, B. A., 518; clinical notes on some refractive and muscular cases, Milliken, B. L., 518; several cases in which the vertical diplopia test proved untrustworthy, Theobald, S., 519; an additional note in reference to the case, useful vision maintained by means of a totally dislocated lens, heretofore referred to the society, Theobald, S., 519; a series of wools for the ready detection of color blindness, Oliver, C. A., 519; gouty retinitis, choro-retinitis and neuro-retinitis, Bull, C. S., 519; retinitis punctata albescens, Standish, M., 520; removal of hard cataract by suction, Howe, L., 520; the artificial ripening of cataract, Jackson, E., 520; a case of traumatic dislocation of the iris under the unbroken conjunctiva, Knapp, H., 523; removal of steel from the vitreous with the electro-magnet, Holt, E. E., 543; a permanent magnet for use in removing foreign bodies from the cornea, Johnson, W. B., 543; suppression of the visual image, Johnson, W. B., 543; a case of congenital cyst of the orbit with anophthalmus, Harlan, G. C., 544; restoration of the upper eyelid by means of a flap taken from the cheek, 544; a case of recurrent paralysis of the oculo-motor nerve, Jack, E. E., 617, 624; on certain dangers attending the use of atropine and the employment of a new mydriatic, Derby, H., 640; recent progress in ophthalmology, Standish, M., 643.

Fair. Medical exhibits at the World's Fair, 98; the State Board of Health exhibit at Chicago, 125.

Faith Cure. Some results of faith cure, 205.

Fast. A prolonged fast, 550.

Fever. On a simple continued fever, Baumgarten, G., 199; a means of relief in hay fever, 229.

Ferguson, E. D. An additional note on nephrotomy and nephrectomy, 469.

Field, M. D. Detention hospitals for the insane, 400.

Filipovich. A new diagnostic sign in typhoid fever, 429.

Finder, W. Researches on the efficiency of vaccina after typhoid fever, 498.

Fisher, E. D. Congenital cerebral hemiplegia with autopsy, 446.

Flint, A. Fermentative dyspepsia, 471.

Food. Recent progress in foods, drugs and articles of domestic use, Davenport, B. F., 93; the general principles underlying all good methods of infant feeding, Roteh, T. M., 505.

Foot-ball, 524; a temperate word for foot-ball, 546.

Forchheimer, F. The intestinal origin of chlorosis, 200.

Fowler, G. R. The relation of the bacterium commune coli to appendicitis, 549.

Fractures. A method for applying pressure to the seat of a fracture for the purpose of bringing the bony fragments into accurate apposition and retaining them there until consolidation has taken place, Monks, G. H., 63, 73; simultaneous fracture (intra-articular) of both olecranon processes, Boland, E. S., 347, 351.

Frarier. A foreign body mistaken for cancer, 77.

Fuchs. Cryptophthalmus, 50.

Gallant and Coleman. Persistent singultus relieved by lavage of the stomach, 429.

Galloupe, C. W. A consideration of erysipelas occurring during the puerperium, 166.

Ganglion, Jordan, 230.

Gangrene. The pathology, symptoms and treatment of gangrene, 277.

Gastric ulcer, Blake, J. G., 542.

Gay, G. W. Tracheotomy and intubation at the Boston City Hospital, 388; strangulated hernia, 637, 646.

Generative System. Treatment of loss of sexual power by ligation of veins, King, A., 36; the treatment of prostatic hypertrophy, Gerrish, F. H., 44; abdominal hysterectomy for fibroids, with cases, Elliot, J. W., 57, 70; the treatment of prostatitis by ichthyol, 77; the non-operative treatment of salpingo-ovaritis, Shoemaker, 126; hysterectomy for cancer of the cervix by combined abdominal and vaginal dissection, Richardson, M. H., 436; report of progress in gynecology, Davenport, F. H., 441; a case of ovarian tumor; a case of fibroid of the uterus, Mixter, S. J., 445; an epidemic of priapism, Meynier, 549; cancer of the uterus, Richardson, M. H., 567; two cases of acquired complete atresia of the vagina, Kingman, R. A., 615; a peculiar case of acquired atresia of the external os uteri, Hirst, B. C., 616.

Gerrish, F. H. The need of agreement on the limits of the abdominal regions and a proposition for a new method of division, 10, 16; the treatment of prostatic hypertrophy, 44.

Gerster, A. G. How should the general practitioner deal with strangulated hernia? 61, 66.

Giles. The vomiting of pregnancy, 206.

Goldthwait, J. E. Forcible correction of angular deformities of the knee with a report of cases, 242; the treatment of hallux valgus, 533, 542.

Goldziehel. Lymphoma of the conjunctiva, 50.

Gordon, S. C. Salines in appendicitis, 557.

Gorilla. A Chesterfield gorilla," 526.

Gout. Rare forms of gout and rheumatism, Grant, J. A., 497.

Graeser. Jambul in diabetes, 549.

Granger, W. D. Voluntary commitment of the insane to asylums, 497.

Grant, J. A. Rare forms of gout and rheumatism, 497.

"Greater love hath no man than this," 402.

Green, C. M. Recent progress in obstetrics, 118.

Grippe. Sequelæ of la grippe, Aldrich, W. H., 352.

"Growing Pains." 177.

Gruening, E. Sarcoma of the choroid, 518; sarcoma of the eyelid, 518.

Gun-shot Wounds. Trephining for pistol-wounds, von Bergmann, 77; gun-shot wounds of the joint, Burrell, H. L. 369.

Gynecology. Report of progress in gynecology, Davenport, F. H., 441.

Hæmaturia. The significance of hæmaturia, Smith, C. D., 44.

Haig. The causation of anæmia by uric acid, 76.

Hallux valgus, Blodgett, A. N., 579.

Hamburg. Letter from Hamburg, Nash, G. W., 78.

Hammond, C. M. Progressive muscular atrophy, 421.

Hammond, Judge. Medical witnesses and expert testimony, 49.

Harlan, G. C. The relation of the patellar-tendon reflex to some of the ocular reflexes found in general paralysis of the insane, 517; tumor of the iris, probably tubercular, 518; a case of congenital cyst of the orbit with anophthalmus, 544.

Harrington, F. B. A case of acute septicæmia, 169; intra-peritoneal cystotomy, 443.

Hart, E. Visceral phlebotomy, 127.

Hart, E. Dr. Hart's impressions of the medical profession of America, 149; on the "code," 357.

Haven, G. Some cases of laparotomy, 541.

Hay Fever. A means of relief in hay fever, Ferber, 229.

Head. Fracture and injuries to the head, Spear, D. D., 300.

Holt-Stroke treated by chloroform, Koerfer, 179.

Hernia. How should the general practitioner deal with strangulated hernia? Gerster, A. G., 61, 66; strangulated hernia, Gay, G. W., 637, 646.

Herrick. A peculiar cause for urethral hæmorrhage, 333.

Hersom, J. L. Diabetes mellitus, 42.

Heterogeneous personality, Baker, S., 399.

Hill, J. C. Tracheotomy in a case of empyema following pneumonia, 619.

Hills, W. B. Recent progress in medical chemistry, 13.

Hip-Joint. A case of hysterical hip-joint successfully treated by hypnotism, Peckham, F. E., 419; bloodless amputation at the hip-joint, report of cases operated on by the author's method, Wyeth, J. A., 471.

Hirst, B. C. A peculiar case of acquired atresia of the external os uteri, 616.

Hoch. Cause of death in burns, 22.

Holt, E. E. Removal of steel from the vitreous with the electro-magnet, 543.

Homans, J. The remarkable effects of divulsion of the urethra, 641.

Hopkins, F. E. A case of foreign body impacted in the larynx, 417.

Horse hair in minor surgery, Thompson, C. O., 345, 351.

Hospitals. The relation of hospitals to medical education, Hurd, H. M., 141; Boston City Hospital, annual report, 174; isolating wards and hospitals for infectious diseases, Rowe, G. H. M., 385; detention hospitals for the insane, Field, M. D., 400.

Howe, O. T. An extensive injury of the chest, 441; a bad family record, 562.

Howe, L. Removal of hard cataract by suction, 520.

Hurd, E. P. Cholecystotomy followed by cholecysteuterostomy, 382; a case of sudden death in an inebriate, 593.
Hurd, H. M. The relation of hospitals to medical education, 141.
Hygiene, Health and Boards of Health. The State Board of Health exhibit at Chicago, 125; report of the committee appointed to secure from the legislature improved sanitary legislation, 472; Massachusetts State Board of Health, annual report, 1892, 573.
Hypnotism. A case of hysterical hip-joint successfully treated by hypnotism, Peckham, F. E., 419.
Indians. The vital statistics of an Apache Indian community, Borden, W. C., 5.
Infection. Isolating wards and hospitals for infectious diseases, Rowe, G. H. M., 385.
Influenza. Epidemic influenza, 603.
Insane. Voluntary commitment of the insane to asylums, Granger, W. D., 497.
Instruments and Apparatus. A simple substitute for the Leiter coil, Sprague, F. B., 93; a useful method of drainage in supra-pubic cystotomy, Cobb, F., 197; apparatus for fracture of the humerus through or near the deltoid insertion, Adams, Z. B., 198; the subcutaneous injection of salt solution, a substitute for the intravenous method; report of cases and a simple apparatus, Cobb, F., 325; a new pedodynamometer, Krauss, W. C., 446; the male catheter, Ayres, D., 498; a modification of the long traction splint for hip disease, designed to provide a light apparatus for little children, Thorndike, A., 540.
Insurance. Infantile insurance, 355.
International Medical Congress. Postponement of the International Congress, 148.
Intubation. Intubation of the larynx in private practice, results of seventy-eight cases, Whitney, C. M., 341, 350; some more intubation statistics, Stanton, R. J., 606.
Iodoform. Action of iodoform on pus microbes and on the leukocytes, 403; atrophy of the optic nerve following iodoform poisoning, Valude 405.
Itch. The increasing frequency of the itch, Stelwagon, 406.
Jack, E. L. A case of recurrent paralysis of the oculo-motor nerve, 617, 624.
Jack, F. L. Further observations on removal of the stapes, 590.
Jackson, E. The artificial ripening of cataract, 520.
Jackson, H. The complications of scarlet fever as observed in fifty cases, 162, 172.
Jakowski. Ætiology of pleuritis, 150.
Jambul in diabetes, Graeser, 549.
Japan. Hot baths in Japan, 630.
Jaundice. Jaundice from mental emotion, 330.
Jenks, W. F. The William F. Jenks memorial prize, 258.
Johnson, F. W. Pregnancy in the left horn of the uterus, simulating extra-uterine pregnancy: laparotomy, 643.
Johnson, W. B. A permanent magnet for use in removing foreign bodies from the cornea, 543; suppression of the visual image, 543.
Johnson & Johnson. "The misuse of drugs in modern practice," 430.
Joints. Gun-shot wounds of the joint, Burrell, H. L., 369.
Jordan. Ganglion, 230.
Josserand. Hysterical hæmatemesis, 49.
Judson, A. B. The importance of early attention to the disability caused by infantile paralysis, 614.
Jurisprudence. The pathological conditions of the heart which result in sudden death, Councilman, W. T., 457, 472; rights and duties of medical examiners in the investigation of certain cases of homicide, Dolan, 472.
Kenefick, T. A. Abscess in the cerebellum, 144.
King, A. Treatment of loss of sexual power by ligation of veins, 36.

LECTURES ON SURGERY.

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

X.

SPECIAL FRACTURES.[1]

THE head of the Radius receives a good many blows. It is quite exposed. The outer condyle does not shield it very well; and it gets a rap frequently. Fracture of its neck is extremely rare. It can be diagnosticated, if present, by putting the arm in the flexed position. Get the thumb on the head of the radius, rotate and see whether the head rotates, or whether we get crepitus. If a fracture exists, it is to be treated on the internal angular splint; the arm to be kept quiet and prevented from supination or pronation for two or three weeks, and then passive motion is to be used.

The more common injuries of the head of the radius are of two kinds: one is partial dislocation of the head of the radius, which occurs in infants and very young children, and is ordinarily produced by the nurse's lifting the child by the wrist. It is a most pernicious practice. The immense weight below acts as a great leverage, pulls upon the radius, and presently the child drops its arm. It will not rotate; it will not pronate or supinate; and there is a slight projection of the radius at the joint. This injury is common in very young children; and it is thought to be a sprain, and frequently overlooked. It is not a fracture; it is not a thorough dislocation; it is a partial dislocation, with subsequent inflammation about the head of the radius.

The child should be etherized, and extension gone through with, and the head of the radius be rotated, and pushed back into place. Use fomentations a few days, and the child recovers.

The other injury is stellate fracture of the head of the radius. The patient must receive that injury in a very peculiar way. It may occur in connection, possibly, with Colles's fracture; at any rate it is probably produced by the same sort of violence. When a person breaks the radius about the wrist, he frequently does it while attempting to save himself from falling. Falling directly upon the palms, transmitting the force upwards, may drive the head of the radius also against the condyle, and cause the injury of stellate fracture of the articular surface. This is an obscure injury. The patient is lame, sore, he cannot rotate, supinate or pronate. There is an obscure rubbing sound more like tendon than bone. If we are sure that the head of the radius is in place, sure that it rotates under the finger, and can eliminate fracture of the shaft of the radius, and the symptoms continue, we may conclude we have a crack through the head of the radius. The only consequence about knowing whether it is so or not, is as to treatment and prognosis.

Rest will restore it; and restoration of the part will be quite complete, if we give it time. Put it in a sling; foment it and allow it to heal. Yet it will be slower of recovery than a simple sprain.

By far the most common injury of the radius is the break just above the lower epiphysis, usually at the junction of the shaft and the cancellous portion, or about three-fourths of an inch above the wrist. This occurs most frequently by falls upon the hand, and is very often an impacted fracture, unlike other features of the upper extremity. An impacted fracture — why it is so, you see by looking at these sections of the bone, showing where the shaft comes down and terminates in this expanded cancellous portion; and when the break occurs, the shaft is driven into the cancellous tissue. It is never driven in without displacement, generally antero-posterior, giving rise to marked deformity.

The other fracture of the lower end of the radius is a complete fracture; and when that occurs, the lower end of the bone rides considerably out of place and the hand goes with it. The peculiar prominence of the styloid process of the ulna, which is so marked in the thin arm, vanishes; and instead of that it reappears as a projection upon the ulna side. The natural projection of the styloid process is gone; and what appears to be styloid process is a partial dislocation of the ulna. The whole hand drops over to the radial side. The antero-posterior displacement is very marked indeed, giving that peculiar appearance of the two curves called the silver-spoon deformity.

The first thing to attract attention is the loss of prominence of the styloid process of the ulna. When you find that gone, you may be pretty sure that fracture of the radius has taken place. Next, you look underneath and find all the natural hollows of the wrist obliterated, and great protrusion where the wrist should be; and further back you find another antero-posterior projection. If a complete fracture, in a little while you find the ulna pushing out to the ulna side, the antero-posterior deformity being the most marked.

The first and most important question in recognizing this fracture; which by the way is overlooked about as often as any fracture in the body and usually considered, when overlooked, to be sprain of the wrist; the great point, I say, to be made out when you make the diagnosis that there is a fracture of the lower end of the radius, is whether it is an impacted fracture, or a complete fracture. The complete fracture, by a little force, is easily drawn into place, so that the natural outlines are at once restored. If an impacted fracture, you draw down and the deformity remains the same; and it will remain so always unless it is broken up by force. Why not leave it as it is? The deformity is not great. Is it not improper treatment to pull it apart thereby delaying union, it being known to be one of the worst possible practices in surgery to interfere with impaction of the neck of the thigh-bone? Unfortunately, if this fracture is left unreduced, subsequent stiffness, deformity, neuralgia of the hand are sure to result, because projection and pressure on the nerves and numerous flexor tendons here leads to so much displacement and effusion, that neuralgia of the ulnar nerve is extremely common, and great stiffness, and loss of power and strength in the use of the hand itself. There are then very important reasons why this impaction should be broken up. Now simple extension and counter-extension wont do it. You have got to exert great force, and it is better to give ether for it. The arm being seized, and the hand extended and bent towards the palm, you compress the fragments with the thumb, and force them down until you break up the impaction — are conscious of lateral motion and complete fracture; and then you pull the parts into place. Then you have converted a partial into a com-

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

plete fracture; and the treatment for the complete fracture becomes the same for all that class of cases.

The important point would seem to be in treating these fractures not to press the back of the wrist down in such a way, by splints, that we shall lose sight of this arch, which is so marked, under the radius. If we force this bone down so that it lies on a flat surface, we do not have a good result. This arch must be well supported; and in addition to that, the best position is one midway between pronation and supination, with the hand bent over a roller, leaving two joints of the thumb and all the joints of the fingers free to move.

Mr. Colles, of Dublin, gave his name to this fracture, and first accurately described some of its peculiarities. It almost always occurs from one-half to three-fourths of an inch above the carpal end of the radius, where the hard shaft of the bone meets the soft cancellous tissue. We said it was frequently impacted, though sometimes a complete fracture. I did not say at the last lecture what ought to be said, that this is one of the very difficult fractures to treat and get a perfect result. It is not quite so much so as the collar-bone, for the collar-bone almost always results in some deformity when the fracture is anywhere near the middle of the bone; but, on the other hand, although the deformity at the wrist from this fracture may not be so great, yet its consequences are much more disastrous. A lump upon the collar-bone, which will shorten the shoulder, is of little account except for the looks; on the other hand, the marked deformity from bad union of fracture of the radius is conspicuous, impairs the mobility of the flexor tendons, weakens the ligaments, and frequently gives rise to persistent neuralgic or rheumatic pains, we can hardly say which.

It seems to me the three essential points in treating are: first, diagnosis, for the fracture is frequently overlooked and mistaken for a sprain, with disastrous results. Next, if it is to be set, it must be set at the first visit, or it is never set afterwards. Successful reduction of the impaction and getting the bones into their proper position, or the fragments of bone into their proper position, is the second great *sine qua non*. And the third one is, that in order to prevent future stiffness of the tendons, confinement of the fingers and thumbs should never take place under the splint; but the splint should terminate at the head of the metacarpal bones, and the thumb and fingers should be left free.

Careful diagnosis, reducing impaction and deformity, subsequently leaving the fingers and thumb somewhat loose and free, seem to be the essential points in order to get a good result.

In spite of all this, and in spite of the most careful treatment, subsequent troubles occasionally arise; and they arise, if the bone has been properly set, in two ways. If the patient is old, and subsequently rheumatism of the fibrous tissues about the joint is set up, rheumatic adhesions and stiffness take place in the sheaths of the tendons; large effusions occur about the palmar surface of the wrist, and on the dorsum, which are not readily absorbed; and loss of perfect motion of the fingers and thumb frequently results in the old, although the fracture may do perfectly well. So we must give a guarded prognosis in the elderly person. The other cause of imperfect restoration is of an entirely different character, and exists usually in younger subjects, though sometimes in middle-aged subjects, but most frequently in females. It is due to the fact that the radio-ulnar ligaments which attach the radius to the ulna; also the lateral ligaments of the wrist-joint, which attach the bones of the forearm to the bones of the wrist, are ruptured, or stretched and sprained, at the time of the fracture, so that the hand is partially dislocated at the wrist; and they do not recover their firmness and contractility perfectly in every case. This is the class of cases in which the following result will be observed to take place. An ordinary Colles's fracture having occurred, diagnosis having been made, the bone thoroughly set, it comes out of the splints in good position and apparently with an excellent result. The patient is lost sight of, but returns in a few weeks, or months, with lateral displacement of the ulna, partial dislocation of the wrist, and looseness or limpness of the whole articulation. This is due to want of restoration of the ligamentous union. It does not recover its firmness and elasticity so quickly, if at all, as the bone; and this is not noticed, in some subjects, for the first few weeks. For this condition the surgeon should hardly be held responsible; neither should he be held responsible for the rheumatic condition, which sometimes follows. All that he is properly responsible for is to make a diagnosis; to be sure that he reduces the impaction and gets the bones into their proper position; and, subsequently, for a reasonably careful treatment. In the large majority of cases a very fair hand will result — a perfect one in some cases; an imperfect one, according to surgical authorities, in some cases, in spite of the best treatment.

Non-union is not to be dreaded. Union usually takes place, generally within three weeks, and at four weeks is well consolidated; so that we have not that danger to fear. We have rather the danger to fear of imperfectly matched fragments, subsequent distortion, stiffness of the fingers, subsequent relaxation of the ligaments.

We spoke of the fact that this was almost the only case in which it was proper to seize an impacted fracture and break it down and restore the fragments to place. The fact that union is almost sure to occur makes us the more bold to do this; and what we would not venture on in fracture of the neck of the thigh-bone, we may do with safety at the wrist.

The mistake that is made in the diagnosis in these cases is, almost always, that the patient has sustained nothing but a sprain. If seen before great swelling has come on, the peculiar arch-shape of the wrist may make us suspect fracture. Suppose, after all the skill we can expend, the diagnosis is uncertain; it is the wisest plan to treat as if a fracture certainly existed. Draw the parts into place; put them on a splint, and keep them confined a reasonable length of time. Many patients will not submit to this; and many patients do not seek the aid of the doctor. If, however, we have a chance to treat the case, and cannot make a sure diagnosis, we had better treat it as if it were a fracture for two or three weeks; being sure that the treatment of a sprain, in that way, will not be impeded; while, if there is a fracture, we shall get a good result for the patient.

On account of the lateral deformity in the complete fracture of the radius, surgeons were led to employ splints which should press the ulna back into place; and M. Nélaton invented one called the pistol-shaped splint. In that way, by drawing the hand over to the ulna side, the ulna is forced back perfectly into place.

Unfortunately this entails other troubles, which make it a bad mode of treatment to adopt. The great strain put upon the lateral ligament, on the radial side, results usually in a weak wrist, and imperfect restoration of the hand back to its normal position, when the splint is taken off. This splint is now seldom used.

I spoke of the arch under the radius, that it should be well supported by a splint running up under it. No splint is so comfortable as that sometimes called Bolles's splint, or Smith's splint; splints which have been invented here, and used in our hospital a good deal. I would also name Carr's splint, as fulfilling the same indications. Some people go so far as to treat this fracture without splints, saying if the hand is put firmly in this position with adhesive plaster, a very good result will occur. It is not sufficiently sure as a method of treatment to render it safe to pursue it. You must bear in mind, in all these cases of doubtful result, that you not only want to do the best thing for your patient, but have, to a reasonable degree, to guard yourself against any future charge of having failed to do this or that, which usage has rendered the proper thing to do in the large majority of cases; consequently, unless some very distinct advantage can be shown by a new method of treatment, it is better to use that which has been approved by long experience. The patient is in no way so comfortable as upon a splint, even with a sprain; and in fracture, it seems to be doubly necessary.

The splint must not extend below the head of the metacarpal bones; and the dorsal splint should terminate over the projection of the os magnum; and then fingers and thumb will be left freely to play. If there is much distortion of the ulna, a little pad may be applied, by which the ulna may be pushed in; but that is not always necessary, though it is sometimes. The splint should be seen and watched as to tightness within twelve to twenty-four hours; probably taken off once or twice in the first three or four days, in order to loosen and tighten, as swelling increases or diminishes. The dorsal splint should be lifted off at the end of a week; bandages undone; hand allowed to rest on the roller splint; and the patient should be encouraged to manipulate a little, to see if everything is loose and free. Again, at the end of another week; and at the end of three weeks, it is customary to take off the dorsal splint altogether, leaving the hand upon the roller, and the under splint only, but bandaged. At the end of four weeks it is safe to take off all the splints, and allow the hand to lie in a sling. You will find one curious thing in regard to all patients, that while they resist and suffer at first from the irksomeness of splints, after two or three weeks they become so dependent upon them, that they are very reluctant to have them taken away. Now comes the time when the surgeon must take the initiative; and if it is a fracture and has united, he must encourage the patient to take off the splint and use the arm. All splints and bandages necessarily atrophy the muscles, and stiffen up all the joints which are connected. The joints become immovable; and this is, in itself, an evil to be got rid of, as soon as union has taken place. This is the case in any fracture, as well as in this fracture of the radius.

Union almost always occurs. Faulty union may occur; and sometimes the question comes up whether it is wisest to re-fracture the part in order to get a better result. If there is much deformity, if there is persistent neuralgia, is it safe to re-fracture the part? After a longer period than five weeks it is extremely difficult to break it over again. Although occasionally it is done under ether, yet frequently the bones give way in a new place; and you have a badly united fracture and a new fracture, instead of the original injury. In children, we may, in four or five weeks, very well re-fracture and re-set the arm; in older people we have to be more cautious; and after a month or so has elapsed, it is wiser to say to the patient, "You probably have got a better result than you would get by re-fracture." State to him the possibilities.

After the splints are off and the sling is used, the patient must be encouraged to use the hand and arm, and have the motions of supination and pronation, as well as those of flexion and extension made; and it is in these cases, subsequently, that massage and electricity are of great use.

This is a troublesome fracture. It is one of the most common fractures we have to treat. Every one should know how to take care of it. The essentials are; first, diagnosis; next, reducing the impaction, getting the part back to its normal look in every way; and, third, not confining the fingers and thumb in a splint, so that resulting good use of them may occur.

Fracture of the Ulna. — Occasionally the ulna is broken, somewhere about its middle, or anywhere along its shaft. It may be broken by a direct blow, because it is a superficial bone as the tibia is. It is directly under the skin. It is a transverse fracture usually. There is very little displacement, and what displacement there is usually consists in bowing towards the ulnar side, inwards.

It is easily reduced, and very easily treated, and usually unites well. It is not worth while to take up much time with fracture of the shaft of the ulna.

Fracture of the Coronoid Process. — Fracture of the coronoid process is so rare that some surgeons have doubted it; and very few specimens of it exist in any museum. It is to be borne in mind, that in the original growth of the bone the coronoid process is not an epiphysis, and has no natural tendency to separate.

A very peculiar force must be exerted to break it, buried, as it is, in the muscles of the arm; and when it is broken, the upper fragment will be lifted up towards the humerus by the attachment of the brachialis anticus muscle. The joint is unlocked at once. Dislocation backwards takes place. Then the question is, Is it a simple dislocation, or is there any bone broken which normally holds the joint in place? Of course, we go through all the manœuvres of reducing dislocation and getting it into position, and see if it will stay there. If the coronoid process is broken off, it will not usually stay in place.

The treatment is simple. It is the internal angular splint with a firm pad in the bend of the elbow to compress the coronoid process down into place. If we are satisfied that this fracture exists, and if that treatment is adopted, you must see, that treatment should be carried on a good while, to secure consolidation of this little piece of bone against the efforts of the brachialis anticus to draw it out of its place in every movement of the arm. The splint should be kept on five or six weeks. Neither would it do at a very early stage to use flexion; but the accident is so rare that we need not consider it very much.

On the other hand, the olecranon is an epiphysis; it separates easily in childhood, and breaks off easily in

the adult, from a fall occurring exactly in the right direction upon the very tip of the elbow. It breaks transversely. To the olecranon process is attached the tendon of the long extensor of the arm, the triceps; and its natural tendency is to pull this fragment up on the back of the humerus. This displacement, however, does not usually occur at first, on the receipt of the fracture; and it is a point on which I wish to insist, because fracture of the olecranon is occasionally overlooked, when it has occurred, during the first few hours, from the fact that great displacement is expected and is not found. In many of these cases you will find, that when you first see the patient, all you can detect across the back of the elbow is a chink in which you can barely put the thumb nail; but by seizing the little fragment and moving the arm, you may make sure of crepitus. If you see it after twenty-four hours, you will frequently find a separation, so that you can lay the little finger between the fragment and the bone itself. The fragment has ridden up quite a distance on the back of the humerus; but this does not take place, at once, on the receipt of the injury.

It is broken across transversely, lies in place. The patient keeps the arm still to resist pain. Slowly the triceps contracts; and if treatment is not administered, after a little while it draws it out of place, and then you can detect it.

In its future slowness to unite, and its imperfect union, the olecranon may be compared to the patella. In many cases nothing but ligamentous union occurs; in some few cases bony union. Ligamentous union is extremely strong and useful, however; and the patient gets along very well, though there may be a slight separation of the fragments.

It is obvious that in order to restore the bone to its normal place the arm must be in the extended position. The moment you begin to bend, it separates and rides up upon the humerus.

Now to get the most perfect result in the way of union, the old treatment, which is still used by many, was to treat it on a perfectly straight inside splint; the patient carrying his arm about extended; the splint going down to the palm and up to the axilla, just as we would splint a broken thigh. It is rather disastrous in its effects. The parts are held in an extremely awkward position. It is a long while before we can venture to get flexion of the elbow; and it is doubtful if the patient gets as good a result as he does in another way.

Among the many wise observations of Hippocrates, there is described his mode of treating fracture of the olecranon, which is practically the mode we are coming back to. He said that there was ligamentous union; that if we kept the arm too straight and stiff it could not be used very well afterwards. The typical way would appear to be to put on a splint at a very obtuse angle, with a screw to enable you to move it a little every few days. In addition to this, a good deal can be gained in holding the fragment in place by a figure-of-8 bandage of adhesive plaster, just as you hold the fragments of the knee-pan in place, by the figure-of-8 bandage.

Pad in the bend of the elbow, figure-of-8 bandage, slightly obtuse angle, and an adjustable splint, seem to give the best results in fracture of the olecranon. This is especially true in the old person; and most of these fractures happen in the old, because in them the bone is brittle. They are apt to fall on the very point of the elbow; and in them, six weeks' confinement in an extended position entails disastrous anchylosis; whereas the partially obtuse angle position, with slight mobility, produces a better result; and even if they have ligamentous union only, they will have, on the whole, a more useful arm.

This fracture, however treated, has got to be a slow affair; eight weeks probably. It will not unite firmly until a considerable length of time has elapsed. So much the stronger reason to have the ability to give a slight motion to the joint, from day to day, after treatment has progressed for two or three weeks.

Fracture of the Radius and Ulna. — Fracture of both bones of the forearm is subject to a variety of disasters. We spoke the other day of the fact that the radius was necessarily twisted out of place by its supinators and pronators according to the site of the fracture, and it was very difficult to get these two fragments to lie in an exact line; and in fracture of both bones of the forearm it is practically found that the ulna is held in position, unites promptly, acts as a splint to the other bone; and the other bone, if it unites, usually unites with a distortion, and later than the ulna does. Then another trouble is liable to arise, which is, if the fractures happen to be about the same line, the radial fracture may be drawn pretty nearly into contact with the ulna fracture, and in the effort of nature to repair the broken bones she may build a bridge across from radius to ulna, and if that occurs, the radius is tied to the ulna, and the entire power of supination and pronation is forever lost. In what position of the forearm do they lie best apart in order to avoid this contingency? We see at a glance that pronation would be a very fatal position, that extreme supination also is a very bad position; that midway between the two, the bones are most thoroughly apart; therefore, in treating fractures of the forearm mid-pronation is practically the best thing. This, fortunately, is the position which the patient always assumes, if left alone.

Suppose we have this fracture, try to get it into place, push the arm into this position, and hold it by two antero-posterior splints. If those splints are narrow, the result of the bandaging will be to crowd the bones in together; consequently, in treating fractures of the forearm, where both bones are broken, it is desirable that the splint should be a good deal wider than the outer lines of the bones themselves. The whole arm should be flattened down between two broad boards, and held in a semipronated position. Splints have been contrived — perfectly useless, however — and various padding has been contrived, with the idea of pressing apart the bones, preventing them from pushing together, by a ridge on one of the splints, or a pad put between the splints, in a peculiar way. This does not succeed. It cannot press down the two layers of muscles. It only leads to some distress, irritation or sloughing from pressure on the parts themselves, and does not practically do much good.

Union of the ulna is prompt. Union of the radius is slower. Once the ulna joins, it acts as a splint.

There is one great danger of this fracture which has not been alluded to yet, and it applies in a certain degree to all fractures, that is the chance of stopping the circulation and causing sloughing and gangrene from too close bandaging of the parts. It is especially liable to occur in this case, because we have here two bones united by firm interosseus membrane. There

are two layers of flexor muscles, in and among which are veins, arteries and nerves. Compression may be very easily applied, with sufficient force to restrain the circulation to a disastrous degree, by bandaging the forearm tightly, because in so doing you press these tender parts upon an immovable posterior wall which cannot retreat and is not elastic; that wall being made up of the two bones and interosseus membrane; and cases of gangrene have occurred under this treatment in this fracture. Before, perhaps, the mischief can be recognized, mortification of the hand or tips of the fingers occurs — an extremely disastrous result for the patient, and for the doctor who happens to treat the case. Here, again, we see the safety of broad splints. You cannot very well compress the arm disastrously with broad splints unless you use extreme force. And here, again, let me speak of another point, and that is in reference to the way in which bandages should be applied where splints are required. It is this, a roller bandage should never be applied next to the injured or broken limb, but padding and sheet-wadding and splints should be applied first, and the bandage applied outside. This may seem idle to speak of. It is, however, occasionally done with the most disastrous results, because there is nothing to prevent this roller from constricting the swelling parts, and sloughing is liable to take place; whereas, if the splints are put on first and the bandage afterwards, the chances of obstructing the circulation are much less.

Non-union is to be dreaded here. Non-union of both bones is not very rare. It gives rise, when it occurs, to a useless arm. There is a false joint, and but little can be done with the arm. When this occurs you have two alternatives. One is a serious operation — cutting down upon the ends of the bones, scraping back the periosteum, sawing off the rounded parts, shortening up the forearm, fastening the two ends of the bones together, and treating it as a compound fracture. You may frequently get a good result in this way. It is a somewhat risky mode of procedure. If the patient does not wish to do this, if he has not the constitution to stand it or is too old, you have another resource, — to keep the arm permanently in splints. The splint is the internal angular splint with a flexible elbow, padded with chamois. The patient puts it on and off, bathes the arm, keeps it healthy. That does very well. The other is the only way to make the parts unite.

Fracture of the Carpus. — Fractures of the carpus are rare unless they are compound. The treatment is to push back the broken bones into place; bandage lightly on a splint; look out for effusion. These are usually compound fractures. The bones of the carpus are rarely broken except by some crushing violence, which has broken through the tissues.

Fracture of the Metacarpal Bones. — Fractures of the metacarpal bones, on the other hand, are not uncommon, and the most frequent place for them is near the knuckle, near the distal end of the metacarpal bone. Occasionally the metacarpal bone of the fifth finger on the ulna side is broken at the middle from a blow. Once in a while in consequence of a severe blow this large second bone is broken; but the usual fractures are down near the distal end, towards the phalanges.

The best way to examine the two hands is to shut them and look at the knuckles. We see, often, a knuckle missing where there is a fracture. We say, at first, that there is a dislocation, that the finger has gone backwards into the palm; on the other hand, it is a fracture, and the head of the metacarpal bone and finger have dropped together. Put your finger underneath and press up, and it comes up into place and the line is restored; and by manipulation we can find crepitus, and be sure of the fracture.

This indicates the line of treatment to be pursued in fractures near these distal ends. Support must be from below. Putting the hand over a ball is good treatment. A large splint that holds the whole palm is also good treatment.

Union is slow. If you discontinue treatment too soon the bone sags, and subsequent deformity results.

Fractures of the Fingers. — Fractures of the fingers, phalanges, are, of course, easily recognized and easily treated. The point to be borne in mind is that there is liable to be deformity in two directions, as the finger recovers. We all recognize and try to treat, and usually succeed in treating well, the antero-posterior deformity of broken finger; but the lateral deformity is to be looked out for as much; and you must have the finger set straight in both directions, to get a good result. If you use little wooden splints to support the phalanges, you need four. If you use tin splints, they should be such as to support it below and on the sides. You must look to it that the finger is got perfectly straight, and not allowed to deviate to one side as the treatment goes on.

The finger bones unite quickly; and non-union is not to be feared. The only thing to be feared is, when the fracture is very near the joint, that we may have some resulting stiffness, and not have the perfect use of the flexor or extensor tendon.

THE VITAL STATISTICS OF AN APACHE INDIAN COMMUNITY.

BY W. C. BORDEN, M.D.,
Captain, Medical Department, United States Army.

These statistics are of a community of nearly pure-blooded Indians living in abnormal environment.

As accurate vital statistics of American Indians are rare, if not unknown, this, and the fact that they show the effect of changed environment upon a nomadic people, give these statistics their particular interest. The lack of other accurate statistics of Indian communities gives no normal averages for purposes of comparison, making it impossible to determine the exact amount of divergence from usual rates which changed environment has caused in this community.

The extent of the effect produced must, therefore, remain inferential; but that there has been a decided departure from the normal will be plainly seen from the statistics themselves. These statistics, which are for a period of five years, from July 1, 1887, to June 20, 1892, were compiled by the writer from the official records of the military post at Mount Vernon Barracks, Ala., while on duty there during the summer of 1892, and are those of the Apache Indians now kept there under military supervision and control. This Indian community numbers about four hundred, men, women and children (see Table I), and is composed of various Apache bands, among them being the noted Geronimo and his followers, of Arizona fame.

The Apaches have lived for generations in Arizona and the adjacent parts of Old and New Mexico, becoming thereby constitutionally adapted to the dry, rarefied air and clear, diathermic atmosphere of the elevated regions of the southwestern part of the United States.

They are essentially nomadic and warlike in habit, and deserving of their appellation "Ishmaelites of the West"; they have not only been notoriously hostile to the whites but to alien Indian tribes as well.

This hostility to, and non-affiliation with aliens, has kept these Indians remarkably free from an admixture of foreign blood; so much so, that in this community of about four hundred, there are but five persons in whom white blood can be traced. In 1886, after numerous outbreaks and hostilities and their capture by United States troops, the Indians now forming this community were removed from Arizona and taken to Fort Marion and Fort Pickens, Fla. They remained there but a few months, and, in April, 1887, they were removed to Mount Vernon Barracks, where they now are.

Their condition during their stay in Florida was extremely bad. Brought in from the fatigues of the war-path and the destitution of their hunted camps, they were taken from the clear, dry and rarefied air of Arizona to the humid atmosphere and debilitating climate of the Florida sea-coast. They were supplied with rations and clothing, but were crowded into damp and improperly ventilated quarters.

Here the first effects of such radical change of environment began to manifest themselves, and clearly pointed to the necessity of an attempt to better their condition. Their removal to Mount Vernon Barracks effected a temporary improvement; as on their arrival there, they were placed in tents while a village of log cabins for their occupancy was being built. This village was completed before the end of the year; but the cabins were of the worst type of construction, and the site was unsanitary, being in a low, damp hollow so shaded by trees that free circulation of air and penetration of sunlight were greatly interfered with — a serious matter where, as in Southern Alabama, the humidity of the atmosphere is great and the rain-fall excessive.

They lived in this village for four years, during which time its condition and the health of the Indians became so bad that finally it was found necessary to build another; and in 1891, a much better village of framed houses was built on a hill near by, where the disadvantages of the old site did not obtain. In May of the same year, 46 of the able-bodied men were enlisted as privates in the United States Army, forming Company I, Twelfth Infantry, which was increased by the arrival of 32 Tonto Apaches from Arizona, some two months later. Captain W. W. Wotherspoon, U. S. A., who had been placed in charge of the Indians shortly before, and by whose efforts the building of the new village was undertaken, was given command of the company, and ably instituted reforms in the general and sanitary condition of the community. A commodious barrack was built for the Indian enlisted men; and a hospital with male and female wards was completed the same year. By these means the condition of the community was greatly improved.

In fact, as regards its sanitary condition during the five years for which statistics are given, there are two distinct periods.

During the first period of about four years, they lived under the unsanitary conditions of bad location, wretched habitation and accumulating filth. Their village was on a damp and overshaded soil, and their cabins were of the worst construction. They were built of rough logs, with mud or rough board floors, and with windows too small to admit sufficient sunlight. The roofs leaked, and the crevices between the logs were imperfectly closed. They, therefore, afforded but poor protection against the inclemency of the weather, and were damp, gloomy, dirty, and in every way unsanitary. The Indians being unused to living in permanent dwellings, allowed dirt to accumulate in and about them, as they were accustomed to do with their temporary "wickyups" in Arizona. The latter however, being frail structures of poles and brush-wood lasted but a short time, and were generally abandoned before dirt had accumulated to an unsanitary extent, while the cabins, being permanent, gradually accumulated filth until they became veritable incubators of disease.

The Indians themselves were in no better condition than their habitations. They received regular and abundant issues of rations and clothing; but as none of them were regularly employed at paid labor, they were without money, and, although forbidden, they sold all they could of both food and clothing to obtain it. The money so received they spent to no advantage to themselves.

Captivity, unaccustomed restraint and enforced idleness operated to prevent the mental stimulus of personal endeavor and combined with their unsanitary surroundings to produce a condition of mental and physical demoralization. As a result, the death-rate (see Table I) gradually increased until for the year ending June 30, 1891, it reached the extremely high rate of 142 per 1,000 of living.

During the last period of one year, beginning July 1, 1891, the condition of the community was improved in all ways.

Their new village being on the crest of a hill has plenty of sunlight and free circulation of air. The houses are of fairly good construction, are well lighted by good-sized windows, are plainly built, and are easily kept clean.

The enlistment of many of the men, and the employment of most of the others at paid labor about the village and garrison, removed the demoralizing effect of enforced idleness and gave the Indians a mental stimulus the effects of which can hardly be overrated.

They are now well clothed and well supplied with the necessities of life, while cleanliness of person and habitation is enforced by rigid military inspections and method. The Indian company, in neatness and in the well-kept condition of its barrack, compares favorably with any white company in the United States Army.

The improved condition of the community during the last year, over that of the preceding four years, is shown by the following extract from a report of an inspection made by Colonel Charles Page, Medical Director of the Department of the East, in which he says: "The Indian camp and hospital have been much improved and the quarters with surroundings occupied by the prisoners are as clean as those occupied by the soldiers. The transformation from squalor to neat and tidy condition of quarters and grounds is remarkable."

This bettered condition produced a marked effect

upon the mortality of the community and the death-rate fell (see Table I) from 142.58 per 1,000, of the preceding year, to 109.75. The number of deaths from all causes except tuberculosis fell (see Table II) from 35 to 18; and had the deaths from tuberculosis decreased in like ratio, the death-rate would have been lowered remarkably. Instead of this, the deaths from tuberculosis decidedly increased in number — the germs of the disease having been so thoroughly disseminated during the preceding years.

This general description of the condition of these Indians during the five years will make clear the circumstances under which the following statistics were produced:

TABLE I. — *Showing the mean number, according to age and sex, of Apache Indians present at Mount Vernon Barracks, Ala., for each of the five years beginning July* 1, 1887, *and ending June* 30, 1892; *the number of deaths according to age and sex; the number of births; and the birth- and death-rates per* 1,000 *for the same years.*

Year.	Mean number present (corrected for time).				Deaths.				Births.			Death-rate per 1,000.	Birth-rate per 1,000.
	Men.	Women.	Children.*	Total.	Men.	Women.	Children.*	Total.	Males.	Females.	Total.

Mean death-rate for the five years . . .	93.12
Mean birth-rate for the five years . . .	60.19
Excess of deaths over births	63
Excess of female births over male . . .	21

* Under twelve years of age. The division is made at this age, as official record is so kept on account of those over twelve receiving a full ration from the government, while those under that age receive one-half a ration.

The high birth- and death-rates at once attract attention. The mean birth-rate of 60.1 is nearly double that of civilized communities. The general average in European countries for 1882 was 34.1 per 1,000 of population, the lowest rate being 24.8, and the highest 44.6, while the lowest rate of this community during the five years was 43.6, and the highest 86.7.

The mean number of women over twelve years of age, present during the five years, was 171; and as there were 117 births, the number of births during that time was equal to 68.4 per cent. of the mean number of women present, including those past and those who had not reached the menstrual period.

During the year of lowest birth-rate there was one birth to every ten women; and during the year of highest rate, one woman in every five gave birth to a child.

There are two main causes for the high birth-rate: great freedom of union of the sexes, and the practice of polygamy.

By great freedom of union of the sexes, unchastity is not meant, but, as most of the conditions which with a civilized people lead to sexual restraint, do not obtain with these Indians, early union of the sexes occurs, and the ties so formed are easily broken that other connections may be made. Infidelity is rare during their marital alliances, but these alliances are generally broken at the caprice of either party. The wife is usually obtained by purchase; but curiously, the right of the parents, and particularly of the mother, to a daughter so disposed of, does not end with her marriage. The husband only retains her during their approval; and payments of money or other valuables are extorted from him under threat of taking her from him. Curiously, also, the right of the mother seems not to be questioned by the married daughter; and she, obediently and apparently willingly, returns to her parents when, deeming that insufficient tribute is paid, they order her to do so.

Polygamy is practised; and as the women approach the menopause, the men form new ties with younger women. It will be seen that the family is not developed as with civilized people, but that sexual relations are generally formed on the basis of sexual activity.

As shown by Table I, the women are about double the men in number; but the practice of polygamy and of the men taking younger wives when the older are past the child-bearing period, gives as great opportunity for all the women to bear children as there would be in a community where there was an equal number of each sex. In consequence of the excess of women, it must be borne in mind, when comparing the birth-rate of this community with that of a civilized people, that an increase of men would not increase the births, but would decrease the birth-rate.

At the same time, consideration must be given the probability that this condition is a normal one for this and other uncivilized people — the greater exposure of the men from warfare and other conditions of life, probably tending constantly to keep their number reduced below that of the women.

It may be well to state, that it does not follow, because of their practice of polygamy and the ease with which their marriages are made and broken, that these Indians are immoral. Their standard of morals is different from that of a people of higher civilization. It is in keeping with their conditions of life and stage of race development; and judged by it, they have always been considered virtuous. They are quite free from venereal diseases. During the five years there were treated but two cases of syphilis, one case of urethral stricture, one of gleet, and thirteen cases of gonorrhœa. As before stated, there are but five individuals of mixed (Indian and white) blood in the community.

It is claimed by persons having long acquaintance with these Apaches, that they have always practised infanticide of all infants of mixed blood; but as they have never well affiliated with the whites, it is probable that occasion for such practice has been infrequent. During the five years of close observation at Mount Vernon Barracks no instance of such practice has been observed; and but one half-breed child has been born.

What effect, if any, their changed environment has had upon the birth-rate of these people, is difficult of determination.

Their enforced idleness during the first four years, so different from the activity of their former nomadic life, may have had a tendency to increase the rate; but, on the other hand, it would seem that a decreased rate would be produced by the high death-rate and the

increased amount of sickness which would necessarily accompany it.

How high the death-rate was will be seen from Table I, which shows a minimum rate of 48.9, a maximum of 142.5, and a mean of 93.1 per 1,000 of living; so that in spite of the very high birth-rate, the deaths exceeded the births by 63.

The following table shows the causes of death which produced this high rate, and the relative frequency of each cause:

TABLE II. — *Showing the causes of death, the number of deaths from each cause during each year and during the five years, and the percentage of deaths from each cause to the total number of deaths.*

Totals	20	19	43	53	45	180	100.00

This table shows at once that tuberculosis, diarrhœal diseases, and malnutrition of children were the great causes of death.

Of the total of 180 deaths, 78, 43⅓ per cent. were caused by tuberculosis alone; while malnutrition of children and diarrhœal diseases together caused 49 deaths, or 27⅓ per cent. leaving but 53 deaths, or 29⅔ per cent. for all other diseases. It is plain from these figures, that the high death-rate of these Indians is due, primarily, to the prevalence of tuberculosis among them, and secondarily, to diseases of the alimentary organs. The reasons for the prominence of intestinal disease as a cause of death are readily ascertained. Most of the deaths from diarrhœal diseases were of children, as will be seen from the following, which gives the number of adults and of children dying of these diseases:

	Infants.	Adults.	Total.
Acute diarrhœa	21	5	26
Chronic diarrhœa	11	2	13
Totals	32	7	39

So that of the 39 deaths from diarrhœal diseases, the large number of 32, or 82 per cent., were of children. These 32 deaths added to the 10 deaths of children from malnutrition account for 42 of the 180 deaths.

The infant mortality of civilized people is notoriously high; and it is naturally to be expected that with these people the rate would be still higher, as the great causes of infant mortality, namely, ignorance in regard to the proper care and feeding of children, would exist in greater degree. Improper care exists at all times; improper feeding generally does not begin until the time for weaning approaches. It is rare to find an Indian mother who cannot nurse her child, for in the past, in those cases where the child could not be nursed, it died, so, gradually, through the law of the survival of the fittest, a race was produced whose women can nurse their children — a condition general with uncivilized people — the resources of civilization being necessary to produce the common occurrence of deficient mammary function by saving the lives of non-nursing mothers and so transmitting the tendency. But, when weaning occurs, the Indian children pass directly to the diet of the adults; and as the diet range of the Indians is limited, and their knowledge of cooking very imperfect, children with weak digestion are almost sure to contract acute bowel complaints, which, aggravated by continued improper feeding, generally prove fatal.

The improper feeding of children was undoubtedly as common with these Indians previous to their removal from Arizona as it has been since, but other disease-predisposing factors have been added by their change to their present place of abode, which have helped to produce a high infant mortality. In the hot and moist air of summer, which prevails in Southern Alabama during seven months of the year, putrefactive changes quickly occur; the improperly kept and poorly cooked food of the Indians is apt to take such change, and is, consequently, often given to the children when in anything but proper condition. From the elevation of Arizona and New Mexico, the air there is dry, and putrefactive changes are much less apt to occur. There the Indians habitually preserve their meat by drying in the sun and air; but in Southern Alabama meat so treated (and the Indians from habit still attempt to so cure it) almost invariably spoils, and is frequently eaten by them and fed to the children after it has begun to decompose.

To improper feeding is added improper clothing. During the first four years the clothing of the children was insufficient to protect them against the ill effects of temperature changes; and this, together with great dampness of the ground from frequent rains, had great effect in producing, or predisposing to, intestinal catarrhs.

It is probable, therefore, that the change of climate from Arizona to Southern Alabama, together with the unsanitary conditions of the first four years, produced a decided increase of infant mortality from intestinal diseases. But, while the death-rate from these diseases was very high, that from tuberculosis was still

higher; and the effect of changed environment in producing a high death-rate from this disease was most marked. How fatal tuberculosis was, and that it was the main cause of death, is shown by Table II and by the following table or tabulated comparisons:

Table III. — *Showing comparative death-rate for* 1,000 *living.*

	Men.	Women.	Children.	Totals.
Mean number present during the five years	95.4	171.8	118.2	385.4
Died of tuberculosis	21	29	28	78
Died, all other causes	7	24	71	102
Died, all causes	28	53	99	180
Death-rate from tuberculosis,	42.53	32.67	46.1	40.45
Death-rate, all other causes	14.17	27.03	116.8	52.65,
Death-rate, all causes	56.7	59.7	162.9	93.10

Death-rate, England and Wales, all causes, 1881-90 . . 19.15
Death-rate, England and Wales, tuberculosis, 1881-90 . 2.15

The death-rate of the men, women and children from tuberculosis is remarkably similar for so small a number of observations, and shows how uniformly fatal the disease has been. While the mean death-rate of the world from tuberculosis is not far from 2 per 1,000 of living, the average death-rate of this community from it has been 40.35. This rate shows the virulency and epidemic quality of this disease in this community; for the rate exceeds that of cholera in the worst infected districts during an epidemic, and is more than four times greater than was the rate from small-pox in London during the years from 1771 to 1781, when the latter disease was at its height.

The high death-rate of the children, from causes other than tuberculosis (116.8), is accounted for by the prevalence of diarrhœal and malnutrition diseases, before referred to.

The death-rate of adults, from causes other than tuberculosis, 14.17 for the men, and 27.03 for the women, is not high, being a mean of only a little over 20 per 1,000 of living, which is about that of the world at large; so that, so far as the adults are concerned, had their mortality-rate from tuberculosis been the usual one of 2 per 1,000, their rate, while high for adults, would have been but 22 per 1,000 of living.

It is generally accepted, however, that the death-rate of Indians from tuberculosis is always greatly increased whenever they are confined to given localities and their usual habits of free life interfered with. Nor can such increased death-rate be considered strange, for, in their natural state, an unconscious adaptation of themselves to their environment has taken place for them by which a normal balance of life is obtained.

The Apaches have lived for generations in the clear, dry, rarefied air of the Rocky Mountain uplands. Their habitations are of the frailest kind, open to the drying air and penetrating sunlight of those regions. From their nomadic habits, they move frequently from place to place, leaving behind them the dirt accumulated by living, and abandoning their frail and soiled habitations for new ones. When one of their number dies, the habitation in which the death occurs is burned, and the belongings of the deceased person are also burned or buried. In this way, by abandonment and burning — natural disinfection methods — communicable diseases, of which tuberculosis is one, were in large part avoided.

Only through long generations of gradual adaptation and natural training can a nomadic people adjust themselves to the living requirements of permanent habitation. With these Indians the experiment was made — unintentional as an experiment, it is true — of taking them suddenly from nomadic life and thrusting them unprepared by previous natural training into a life of quiescence and permanent habitation. The result is shown by the extremely high death-rate, particularly from tuberculosis. The relative frequency with which this disease in its different forms caused death among the men, women and children is given in the following table:

Forms of Tuberculosis.	Deaths from each form.			Totals.	Per cent.
	Men.	Women.	Children.		
Pulmonary	19	27	11	57	73
Enteric	1	2	11	14	17.9
Meningeal	..	..	6	6	7.6
Acute	1	..	..	1	1.2
Totals	21	29	28	78	

The frequency of pulmonary tuberculosis as a cause of death with adults, and of enteric and meningeal forms with children, is noticeable, and in keeping with general observations upon this disease.

The great frequency in children of mesenteric tuberculosis has been frequently observed before, and the ingestion of infected milk has been considered as the main cause. This view seems to be supported by these statistics, as the prevalence of tuberculosis among the mothers would, in this way, produce many cases other than pulmonary even were the children not infected when born.

The great predominance of pulmonary tuberculosis among the adults is also in keeping with general observations — the infection with them generally occurring by way of the lungs.

It is not so plain why deaths from this disease have been proportionately so much greater among the men of this community than among the women, unless it is that the somewhat less active life of the women has given them a certain degree of immunity. It is more probable, however, that this is not the case, and that no such difference would be found if the numbers from which the statistics are derived were larger. In fact, the whole question of immunity to tuberculosis, and of the different susceptibility of different races to this disease, is not yet settled. It is well known that certain races, as the nomads of Persia, Syria and Armenia, and the inhabitants of certain localities, as those of Iceland and the islands of Faroe, Shetland and the Hebrides, are almost, if not entirely free from the disease; while among negroes in this country, and Indians, when under restraint and in contact with civilization, it is particularly prevalent. It is also known that under changed conditions the same race exhibits an apparently varying susceptibility to the disease, as is shown by its appearance among the nomadic races above referred to as soon as they abandon their wandering life.

Also, it is known to vary according to differences in locality or climate; its spread being favored by vitiated and damp air and a moist soil, and retarded by purity and dryness of the air, and a large amount of sunshine. In view of these facts, it seems probable that tuberculosis acts as does any other infectious dis-

ease, being most prevalent where the conditions favoring its spread most obtain; and that the presence of these conditions, more than racial or individual susceptibility, are the important factors favoring its prevalence. This view is supported by the death-rate from this disease of the community under consideration.

For some months previous to their arrival at Mount Vernon Barracks, and during the first four years of their stay there, all the conditions most favorable to the spread of the disease existed; and the deaths from it ran as follows: First year 11, second year 4, third year 18, fourth year 18, fifth year 27.

During the fifth year, though the condition of the Indians was greatly improved, the number of deaths from this disease was greater than before, as the disease had gained such a foothold during the preceding four years that no decrease could be looked for in so short a time. The disease is so slow in development and in running its course, that when unusually prevalent in a community, no sudden return to ordinary rates can be expected, but only a slow decline made possible by most thorough sanitary measures.

Whether the system of disinfection and enforced cleanliness now being carried out in this community together with its bettered condition, will be effective in staying the ravages from this disease remains to be seen, for the unfavorable conditions of changed climate and altered modes of life still remain.

It is to be hoped, however, that this most insidious of diseases can be controlled by the means taken and notwithstanding that the past five years have shown a steady increase of the disease, due to the presence of all the conditions most favorable to its spread, that the following years, through the absence of many of these conditions and the use of suppression methods, may show a steady decline.

Should such decline occur, it will be of interest in that it will show the adaptation of the community to its new environment, and the effectiveness of modern sanitary methods, when enforced.

THE NEED OF AGREEMENT ON THE LIMITS OF THE ABDOMINAL REGIONS, AND A PROPOSITION FOR A NEW METHOD OF DIVISION.[1]

BY FREDERICK HENRY GERRISH, M.D., OF PORTLAND, ME.,
Medical Department of Bowdoin College.

THE surface of the abdomen, as viewed from the front, is very extensive, and presents in the normal condition few features which are at once obvious and constant. Indeed, the only one which is invariable is the navel. The depression called scrobiculus cordis is often lacking; the exact line of the groin must sometimes be searched for with care; the capillary embellishment of the pubes is absent in childhood; the linea alba, the lineæ semilunaris, and the sloping margin of the thorax are frequently obscured by corpulence. The umbilicus alone, while varying in size and depth, is always present. The need, therefore, of some artificial markings to aid in the localization of parts or objects upon, within, or behind the parietes must have been felt by the early students of anatomy. Just at what period any such drawing of lines of latitude and longitude as at present obtains was begun, I am unable to declare, my opportunities for investigating this matter having been too limited to determine the point. It is sufficient for my purpose, as a practical anatomist, to know that such a method has been in vogue for more than a century, and that its universal adoption is evidence of the recognition of its value. Nobody now would wish to be deprived of the terms of convenience which this plan has fastened upon our nomenclature; but doubtless everybody who studies the subject would be glad to have these terms made so definite that there would be no room for doubt as to the exact meaning and the limits of application of each of them. It must be acknowledged, though the confession is not creditable to the scientific pretensions of anatomy, that there is a grievous lack of uniformity in the method of drawing the lines by which the anterior abdominal wall is mapped out into regions.

Having been for a long time annoyed on this account, I have had the curiosity to make a careful examination of the statements of the writers of the works most easily accessible to me, who make any mention of the matter. Though it is quite possible that search through a larger collection would reveal a still greater number of variations on the simple theme, the dozen which I am about to quote abundantly sustain the thought which I have made the title of this essay; and I have, therefore, forborne to make so unnecessary, and hence unwarrantable, a tax upon your patience as more extensive quotation would involve. One does not have to eat a whole cheese to get its flavor.

Before proceeding to a detailed presentation of the facts, it is well to place clearly before us the purpose in view in the creation of these artificial areas. This is so well stated in Quain and Wilson (Pancoast's edition, 1842) that I quote their words:

"The larger or upper compartment of the abdomen is subjected to what may be called a technical subdivision into regions; not that there are any septa or partitions between them, but because of the many important parts which are contained in it, and which require to be minutely described.

"It must be obvious that the very purpose and intent of marking out these lines show that they are not confined to the surface on which they are drawn. They are on the contrary supposed to be projected into so many planes, forming partitions, which divide the cavity into compartments, each containing a certain portion of the abdominal viscera."

Although not every author as distinctly expresses this idea, it is obvious that the conception of projected planes is entertained by all, for otherwise there would be little point in the artificial subdivision of the surface. As Bell says (fourth American from fourth English edition, New York, 1822): "To give greater accuracy to the description of the seat of the viscera, or, perhaps, rather more strictly to connect the knowledge of the internal parts with the outward marks of the belly," is the object of the arbitrary drawing of imaginary lines. All authors speak of certain organs as being situated in specific regions, which, of course, could be true only on the supposition of the extension of the

[1] Read before the Association of American Anatomists at Princeton, N. J., December, 1892.

Last spring, during my annual course of lectures in the Medical Department, Bowdoin College, I told the class of my purpose to read this paper, for which the materials were then substantially collected, at this meeting of the Association. I had never seen or heard of a proposition looking towards agreement on the boundaries of the abdominal regions; and my first knowledge of any such was received after I had forwarded the title of this essay to our Secretary, who immediately kindly informed me of the intention of one of our colleagues to write on the same subject, and sent me a copy of the paper of Professor Anderson. I have, however, not read a line of the latter, in order to be absolutely free from the imputation of plagiarism.

lines straight backward to the posterior wall of the abdomen.

The discrepancy in the drawing of the dividing lines between the various regions is very marked, and almost every possible variation, consistent with the general plan which actuates every method, is presented for our adoption. The greater part of the authors seem to make an effort at exactitude, though with a degree of success which is not altogether admirable; while others content themselves with the establishment of the vaguest boundaries. A good example of the latter class is Fyfe (1800), whose description is worthy of extended quotation:

"It (the abdomen) is distinguished into three Divisions or Regions, termed Upper, Middle, and Under Regions; each of which is subdivided into three others.

"The Upper Region begins opposite to the Cartilage Ensiformis, at a small depression called Scrobiculus Cordis, or Pit of the Stomach, and extends to about a hand-breadth from the Umbilicus or Navel.

"The middle of this Region is termed Epigastrium, or upper part of the Belly, and the two lateral parts Hypochondria, from their lying under the Cartilages of the False Ribs.

"The Middle Region occupies an equal distance above and below the Umbilicus. The middle part of it is called the Umbilical, and its lateral parts the Lumbar Regions or Loins.

"The Under Region begins where the middle one terminates, or at a line drawn between the superior anterior Spinous Processes of the Ossa Ilii, and forms in the middle the Hypogastrium, or bottom of the Belly, and at the sides, the Iliac Regions."

In this description there is not the slightest approach to precision; and the only semblance of such approximation occurs in the implication that the level of the anterior superior supinous processes is a hand's breadth below the navel — an idea which needs no comment, whether a "hand" (four inches) is meant, or the actual breadth of hand of the special person who conducts the measurement. The most that we get out of this account is this: the front surface of the belly is to be considered as mapped out into nine regions of indefinite boundaries and widely varying and undetermined areas.

As a type of the class who attempt accuracy, we may take Quain (1882 edition), who draws the two horizontal lines respectively "at the level of the lowest part of the wall of the thorax," and "between the highest points of the iliac crests"; and the lines dividing these vertically "upwards on each side from the middle of Poupart's ligament."

Between these extremes of vagueness and precision are numerous grades of indistinctness. The upper horizontal line is drawn "opposite the cartilages of the ninth rib," "parallel with the cartilages of the ninth ribs," "over the ninth costal cartilages," "between the cartilages of the tenth ribs," between "the most prominent point of the cartilages of the ribs," "from the inferior margins of the ribs," "across the base of the thorax." The lower horizontal line is drawn "on a level with the most prominent part of the crest of the hip-bone," "the crista of the ilium," and "between the iliac crests."

The lines dividing the zones are made to pass "from the cartilage of the eighth rib to the centre of Poupart's ligament," "from the spines of the pubis to the cartilages of the eighth ribs," and "from the middle of the groin vertically."

At the first glance I may seem to be in error in speaking of the most of these rules as being vague; but my reason for considering them so will be seen when I call attention to the facts that each of the cartilages mentioned presents so extensive a margin as to permit a variation of five centimetres, more or less, for the choice of the student in selecting a starting-point for his measurement; that the anterior margins of the ribs, as distinguished from their cartilages, are practically impossible of ascertainment through their natural coverings; that the most prominent point of the costal cartilages is not the same in different people that there is large room for difference of opinion as to what is the most prominent part of the crest of the ilium; and that "groin" is a word of elastic application.

Some authors give exact directions, but differ vastly among themselves.

An influence which augments the confusion of the student's mind in these premises is exerted by the dictionaries. One says that the epigastrium is "the abdominal wall in front of the stomach," and another, "that part of the abdomen immediately over the stomach and below the diaphragm." One gives the following extraordinary definition of the iliac region: "The side of the abdomen between the ribs and the hips"; and of the umbilical, "That portion of the abdomen two or three inches above, below and on each side of the umbilicus"; and so on, to the great weariness of the spirit.

This dire confusion must suggest the necessity of agreement among anatomical teachers concerning the limits of the regions, which long usage and general consent admit are important. Consequently, I venture to suggest the adoption by this Association, which includes so large a number of the prominent specialists in anatomy in this country, of a system by which these regions may be described uniformly in all of our schools. The influence of our action would be felt abroad, especially if we were to request conference with similar societies in other lands.

The plan which I offer and defend may not meet with your approval; but I trust that some plan will be adopted, as I believe that the credit of modern anatomy requires a radical reform of our present slovenly method.

I propose that the dividing lines be drawn as follows:

The upper horizontal at the level of the lowest point of the inferior margin of the tenth costal cartilage.

The lower horizontal at the level of the anterior superior spinous process of the ilium.

The lines intersecting these from the middle of Poupart's ligament on each side perpendicularly.

In support of this drawing of the upper horizontal, I submit these advantages:

The ease with which the lower margin of the tenth costal cartilage is located.

The perfect definiteness of the directions, which is not attained by mentioning any particular cartilage, without specifying a point upon it.

The anatomical propriety of allowing as large an area as this permits for the upper zone, thus giving a nearer approach to uniformity of width in the three zones.

The fact that this drawing is recommended by some of the ablest authors, such as Bell, Quain and Leidy.

For the lower horizontal line I claim these meritorious points:

Absolute definiteness.

The facility with which the anterior superior spinous process of the ilium is found.

The approximation to uniformity of width of the three zones, which this method ensures.

The localizing of the navel more nearly at the vertical centre of the umbilical region, than is accomplished by having the line pass below the highest points of the iliac crests, as advised by Gray, Quain, Leidy, and others, who thus bring the umbilicus into the lowest part of the region to which it gives the name, and often on the line separating this from the region immediately below.

The fact that this drawing has the support of prominent teachers, like Bell, Owen, Macalister and McClellan.

My arguments for the intersecting lines proposed are as follows:

The middle of Poupart's ligament is easily determined.

The selection of this point is better than that of the bony prominence to which its outer end is attached (as practised by Bell and Cloquet), because we thus cause this line to divide the lowest zone into three regions, as in the case with the upper and middle; and make it divide the other zones much more equally. Only a little room is left for the hypochondriac and lumbar regions if the line is drawn perpendicularly from the anterior superior iliac spine.

The choice of this point is also better than that of the osseous process to which the inner end of the ligament is fastened, as advocated by Macalister and McClellan, because, if the line be drawn perpendicularly, the lateral boundaries of the central region of each zone become too close; and, if it be drawn to the cartilage of the eighth rib, as recommended by these writers, it is less definite, because no point on the cartilage is specified, and it is harder to carry abstractly in mind an account of its obliquity. It is worthy of remark in this connection that the difficulty, upon which I have insisted in the matter of the directions which merely mentions a costal cartilage, is strikingly shown in the picture which accompanies the description of the abdominal regions in that splendid and most recent American addition to our anatomical libraries, wherein we find the text and the drawing in disagreement. If a mistake is so readily made by so painstaking an author, who is also his own artist, in a picture which delineates the cartilages in outline, how difficult it must be for an ordinary practitioner, who is not an expert in anatomy, to avoid such errors in the case of a patient whose thoracic framework is "padded round with flesh and fat."

The perpendicularity of the line is an obvious advantage: first, because it is so simple and, therefore, easy to remember; and, second, because it makes rectangles with the lines which it crosses, and thus contributes to uniformity of outline and comfort of memory. It is true that a line thus drawn will not in all cases strike the same point on the thorax — it will be further away from the linea alba in women than in men, on account of the relatively wider pelvis and narrower chest in the female sex. But no rule in this matter will give absolute results, and the one proposed is as free from disadvantages as any other can be.

There is only one point to remember — the middle of Poupart's ligament. Those who name a point on the chest wall for the other end of the line add an element of difficulty to the task of the student, and can be by no means positive that the resulting line will be vertical. It is a method taught by distinguished anatomists, as Quain and Owen; and others, like Ellis and Gray, make the middle of Poupart's ligament one of the two points between which they draw each of these subdividing lines.

It will be observed that each of the component parts of this plan has the sanction of some illustrious authority; but their association does not occur, as far as I know, in the method of any writer.

In this system only three anatomical points require to be remembered — the lowest point of the tenth costal cartilage, the anterior superior iliac spine, and the middle of Poupart's ligament. I think that it will compare favorably with any other method in respect to theoretical simplicity, accuracy and uniformity of results, and practical applicability.

In this connection it is fitting that something be said about the names which are applied to the different regions.

The central region of the upper zone and the region on each side of it are called respectively epigastric and hypochondriac, by universal usage, except when the cognate terms, epigastrium and hypochondrium, are used. The central area in the middle zone is always named umbilical, and its lateral associates lumbar, by an almost equally unvarying custom. In the lowest zone the central region is generally designated hypogastric or the hypogastrium; but certain authors prefer pubic.

The sanction of ancient custom weighs with me in determining my choice of hypogastric, particularly as it seems to me so desirable to have the word pubic reserved for that area which, in the adult, is covered with hair, and includes not only the lower part of the hypogastric region, but also the bodies of the pubic bones and the structures in front of them.

Iliac is most frequently the adjective applied to the side areas in the lowest zone, though inguinal is preferred by some writers. My choice is the former, inasmuch as a part of the region is not groin, and all of it is neighboring to the hip-bone. Inguinal may well be applied to the long, obliquely situated area, which is located partly above and partly below Poupart's ligament — is, as it were, threaded upon the ligament — and is as much a portion of the thigh as of the abdomen.

In conclusion, a few words may appropriately be spoken in answer to an anticipated objection to this plea for uniformity and accuracy in the delimitation of the abdominal regions.

It has thus far been assumed that the mapping out of regions by imaginary lines is desirable; but I have heard it said that this is useless, because the contents of the designated regions are not the same in all cases.

Considerable variation is admitted; but it is probably not greater than obtains in many other cases in which the desirability of artificial aids to precision is universally admitted. In anatomy we do not look for mathematical accuracy and absolute uniformity, but only for approximations. Our rules are based upon the usual, not upon the invariable. And there seems to me to be no good reason why some uniform method of division of the abdominal surface may not be agreed upon by the anatomical world, which shall be of essential service in the direction of simplification and precision in the description of the relation of the viscera to the parietes and to each other.

DELIMITATION OF ABDOMINAL REGIONS.

BY E. A. BALLOCH, A.M., M.D.,
Medical Department, Howard University, Washington, D. C.

Professor Anderson's communication to the Anatomical Society of Great Britain, in May last, pleading for uniformity in the delimitations of the regions of the abdomen, draws attention to a matter which is of considerable importance to practical anatomists.

As he clearly shows, there is a complete lack of uniformity among anatomists, both as to the boundaries and contents of the region thus artificially outlined. The starting points from which the lines are drawn are likely to vary in position, and no less than fourteen different subdivisions have been made.

Professor Anderson rightly characterizes this confusion as "chaos."

The question is: Can we simplify this subject and agree upon a subdivision acceptable to all?

I take it that our purpose, as teachers, is to adapt anatomy to the daily needs of the practitioner. Now, as a matter of fact, it is my observation that in anatomy, as applied to daily practice, these artificial subdivisions are seldom used.

In treating abdominal diseases or injuries, the practitioner will, in most cases, refer to the umbilicus and the median line of the abdomen as starting points, and designate the lesion with reference to these landmarks. References need only be made to tumors of the pylorus, aneurisms of the abdominal aorta, McBurney's tender point, the incisions for abdominal section, etc. This being the fact, we, as anatomists, should seek to make our artificial divisions of the abdomen conform to the needs of the practitioner as demonstrated by his daily routine.

It must be apparent to all, that the first thing to do is to simplify the division of this region as to number. Nine subdivisions are too many, and this refinement of subdivisions is not needed by those for whose benefit it was presumably made.

Secondly, the boundaries of the subdivisions must be fixed points or, at least, such as are not subject to any great variation in position. Lastly, the subdivisions should be made to conform to the daily needs of the practitioner.

Ophthalmologists have for many years divided the surface of the cornea into quadrants, and lesions in this locality are referred to the upper or lower, outer or inner quadrant, as the case may be, and such reference is perfectly understood by all. So far as I have observed, this plan works well. I see no reason why some such simple subdivision of the abdomen cannot be made.

A line from the symphysis pubis to the ensiform appendix would answer for a vertical, while the horizontal plane could be made at the umbilicus.

The boundaries of these spaces can be outlined with almost equal exactness on the dorsum, where the vertebral column marks the vertical plane, while the horizontal would fall between the third and fourth lumbar vertebræ.

This would give four regions whose boundaries would be reasonably well fixed and not subject to any marked variation. They could be designated as upper and lower, right and left quadrants; and this plan would be an improvement on the present methods of subdivision.

It might be objected to such a division that the vertical plane would bisect the stomach, bladder and uterus, and throw part of these organs into one quadrant and part into another. As to the stomach, this objection lies equally against the present subdivision. As to the bladder and uterus, they are really more pelvic than abdominal viscera, and I think the objection would hardly have much weight from a practical standpoint.

The British Society appointed a committee to consider this matter, with a view to arriving at a uniform plan of delimitation of the regions of the abdomen.

I think we might properly co-operate with this committee, as the question is one equally important to us and to them.

Medical Progress.

RECENT PROGRESS IN MEDICAL CHEMISTRY.

BY WILLIAM B. HILLS, M.D.

FORMATION OF GLYCOGEN FROM DIFFERENT SUGARS.

C. Voit, Otto, Abbott, Lusk, and F. Voit[1] have investigated the formation of glycogen and the changes which sugars undergo in the alimentary canal. From the examination of previous and the present researches on glycogen formation in the liver, it is believed that glycogen may originate in two ways; first, it is a temporary store of carbohydrate food, and secondly, it may be the result of proteid metabolism. The present research was performed on animals (rabbits, hens) in which the hepatic glycogen had been reduced to a minimum by starvation, and relates chiefly to the former of the two sources of glycogen just alluded to. Large doses of different sugars were given. Dextrose lævulose, cane sugar, and maltose increased the hepatic glycogen; lactose and galactose did not, or only very slightly.

Cane sugar and maltose are inverted in the alimentary canal. Lævulose, lactose, and galactose are absorbed as such, and after large doses pass as such into the urine. The liver appears unable to form glycogen from sugars which, like lactose and galactose, do not pass into the condition of either dextrose or lævulose. In fact, these appear to be the only forms of sugar which, when present in the blood, lead to the storage of glycogen in the liver. When subcutaneously injected, the hepatic glycogen rises in amount. No other form of sugar behaves in this way. Regarding lævulose, the liver cells must either form glycogen from it directly or after previously changing it into dextrose.

BEHAVIOR OF LACTOSE AND GALACTOSE IN DIABETICS.

F. Voit[2] finds that lactose causes an increase of the sugar in diabetes. The patient upon whom the experiment was made was taking strict diet, and the amount of sugar in the urine was reduced to a low ebb. The following explanation is given by the author: — Before the sugar was given, the small amount of diabetic sugar in the urine must have originated from proteid

[1] Journal of the Chemical Society, 1892, page 902, from Zeit. Biol., xxviii, page 245.
[2] Loc. cit., 1892, page 903, from Zeit. Biol., xxviii, 353.

metabolism. Lactose appears in the urine more readily than any other form of sugar, not because it is burnt in the organism with greater difficulty, but as it is a form of sugar from which it is not possible for the liver to make glycogen, its "assimilation limit" is low, and so it passes unused into the urine. In fact, in diabetics it appears to be more readily burnt in the body than dextrose, and takes the place of some of the dextrose originating from proteid metabolism. Hence, when lactose is given, a large quantity of dextrose remains unburnt, and passes as such into the urine.

The same results were obtained in experiments with galactose.[3]

PHYSIOLOGICAL ACTION AND CHEMICAL PROPERTIES OF PENTOSES.

In view of the dieting of diabetic patients, W. Ebstein[4] has undertaken to investigate the physiological action of various forms of sugar. The present research relates to the two penta-glucoses or pentoses, xylose and arabinose.

Xylose, dissolved in water or coffee, or in the solid state mixed with the food, was given to various people. It appears that xylose is not assimilated, even when taken in very small quantity, and it can be recognized in the urine within an hour or two after the administration of 0.5 grammes. This is true both for healthy and diabetic persons. One received 25 grammes of xylose; in the next twenty-four hours 9.5 grammes were found in the urine, and the excretion continued for the two following days. Arabinose gave practically the same results. These substances have apparently little or no food value.

Salkowski's[5] experiments on rabbits show that arabinose is absorbed from the alimentary tract very rapidly and completely. It is, however, very slowly oxidized in the system. About one-fifth of the amount ingested is eliminated unaltered with the urine. A small amount can be detected in the blood, a larger amount in the muscular tissue. There is no evidence that glycogen can be directly manufactured from the absorbed pentose. The urine may at times give the characteristic tests for pentoses, as a result of the use of fruits, such as pears, that contain pentosanes, the mother substances of pentoses. This condition must not be confounded with diabetes.

Pentoses reduce Fehling's solution, Nylander's reagent, and form osazones with phenylhydrazine. They also give the following characteristic reactions: (1) By distillation with hydrochloric acid they yield furfuraldehyde. (2) A solution mixed with an equal volume of concentrated hydrochloric acid and then with a solution of phloroglucinol in equal parts of hydrochloric acid and water, and warmed, gives a beautiful red color, which gives a dark absorption band to the right of the D line. Salkowski states that the red color appears first at the surface, and gradually extends down into the liquid; and that the red coloring matter is dissolved on shaking with amyl alcohol. 0.5 per cent. of arabinose can be very easily detected by this test; 0.1 per cent. is recognized only with difficulty.

The amount of pentoses in the urine can be estimated by Fehling's solution, after any glucose that may be present has been removed by fermentation with yeast. 1 milligramme xylose equals 1.9 milligrammes copper; 1 milligramme arabinose equals 1.95 milligrammes copper.

TESTS FOR SUGAR IN THE URINE.

G. Hoppe-Seyler[6] has proposed a new test for sugar in the urine, depending upon the formation of indigo-blue when orthonitrophenylpropiolic acid is boiled with alkalies and reducing substances like dextrose. The test is made by boiling ten drops of the urine for fifteen seconds with 5 c. c. of the reagent (0.5 gramme of the acid and one gramme sodium hydrate in 100 c. c. distilled water). The test serves to detect sugar in urines containing 0.5 per cent. of this substance.

Normal urines do not give a blue color with this reagent, but a green color may be obtained. Albumen does not interfere with the reaction, unless there is more than two per cent. present, when it must be removed by precipitation with lead acetate. The reagent failed to give good quantitative results in the author's experiments.

Gerrard[7] states that when to a volume of Fehling's solution there is added just sufficient potassium cyanide to discharge the blue color, and the liquid is mixed with a second equal volume of Fehling's solution, grape sugar will produce no precipitate in the boiling mixture, but its gradual addition causes a steady disappearance of the blue color, and at the sharp end change the glucose value will be found approximately equal to half that of ordinary Fehling's solution. The author's explanation is, that the double potassium and copper cyanide formed in the first instance, being a solvent of the cuprous oxide, prevents its precipitation when formed by the action of the glucose on the second volume of the Fehling, in which reduction is presumed to take place as in the ordinary method. In practice, he keeps three solutions in separate bottles, as follows: (1) Copper sulphate, 69.3 grammes, water to 500 c. c. (2) Rochelle salt, 175 grammes; sodium hydrate, 76.56 grammes, water to 500 c. c. (3) Potassium cyanide, 33 grammes (or a sufficiency), water to 500 c. c. For testing, 5 c. c. of each solution is mixed with 50 c. c. of water, and to this liquid, boiling in an open vessel, the grape sugar is added until the blue color disappears. In case any precipitate is formed, the cyanide solution must be strengthened.

LOCALIZATION OF MERCURY.

Ullmann[8] finds that the distribution of mercury in the organism always follows the same laws whatever the dose or the form of administration. The largest amount of mercury is found in the kidneys, liver and spleen, in the order given. As regards the digestive tract, the stomach contains very small, but weighable quantities, whilst more is found in the small intestine, and still more in the large intestine. Small weighable quantities are found in the heart and skeletal muscles, and, in individual cases, also in the lungs. The brain, salivary glands, abdominal gland, thyroid gland, bile and bone substance contain unweighable traces, or, with small doses, not even a trace of mercury.

DETECTION OF ATROPINE.

L. Fabris[9] reports the following case. A patient at a hospital in Padua, who had for some time been treated by daily injections of six milligrammes of

strychnine nitrate, died a few hours after receiving an accidental injection of three milligrammes of normal atropine sulphate, exhibiting acute symptoms of atropine poisoning. At the post-mortem, the presence of bilateral mydriasis, and of congestion of the meninges and of the cerebellum became evident. On examining the viscera by the Stas-Otto method, clear indications of the presence of an alkaloid were obtained, but on applying the special reactions for strychnine and atropine, the results were negative. To test the possibility of these alkaloids obscuring each other's reactions, mixtures of three per cent. solutions (the strength of the injections) of strychnine nitrate, and atropine sulphate were tested with sulphuric acid and potassium dichromate, and by Vitali's reaction, with the following results. A mixture of equal parts of the solutions gave the strychnine reaction very clearly, but the atropine reaction not at all; a mixture of one of strychnine with three of atropine gave the strychnine reaction, but not that of atropine; a mixture of one of strychnine with four of atropine gave indistinct reactions for both alkaloids; a mixture of one of strychnine to five of atropine gave a momentary atropine reaction; the characteristic violet coloration is, however, immediately superseded by a reddish tint. Vitali's reaction was not clearly obtained until, at least, nine parts of the atropine solution were added to one of strychnine. It further appeared that a solution of strychnine too dilute to give the characteristic reactions of that alkaloid may effectually obscure the atropine reaction; thus one drop of the three per cent. strychnine solution diluted with ten drops of water scarcely yields the strychnine reaction; on adding four drops of atropine solution to this, no reaction for atropine could be obtained.

A piece of meat injected with 0.05 c. c. of a three per cent. solution of each of the alkaloids, and extracted by the Stas-Otto process, yielded a barely sensible strychnine reaction, and no trace of atropine. Finally, on injecting a mixture of three parts of the three per cent. strychnine solution and one part of the atropine solution into a frog, paralysis of the lower limbs and a great augmentation of the nervous sensibility ensued: on introducing the mixture into the eye of a dog, distinct mydriasis was observed in fifteen minutes. It thus appears that in cases of poisoning by atropine, the physiological evidence may be conclusive when the chemical tests yield doubtful results.

THE ACONITE ALKALOIDS.

W. R. Dunstan [10] in conjunction with E. F. Harrison has continued the research to which reference was made in a previous report.[11] In the present paper, they describe the properties of isaconitine (the alkaloid to which the name *napelline* was assigned provisionally), and the process for separating it from aconitine, and also from another amorphous alkaloid closely resembling it, which has been provisionally named homonapelline.

The investigation of the physiological action of the alkaloids of *A. Napellus* has been undertaken by Professor Cash, of Aberdeen. His investigation is not yet completed, but preliminary results, obtained by a comparison of the physiological action of aconitine and isaconitine, show that the behavior of the two alkaloids, although in some respects similar, is generally distinct. Moreover, whilst aconitine is a most violent poison, even in excessively minute doses, isaconitine is only toxic to small animals when exhibited in comparatively large doses.

[10] Journal of the Chemical Society, 1893, p. 443. Transactions.
[11] Journal, August 11, 1892, p. 138.

ELIMINATION OF CARBONIC OXIDE.

L. De Saint-Martin's [12] experiments show that the elimination of carbonic oxide is at first very rapid, but quickly diminishes, becoming very slight at the end of the third hour. From 5 to 6 per cent. of the absorbed carbonic oxide is, however, never eliminated as such, but undergoes alteration in the living tissues, and is probably converted into carbonic anhydride.

TOXIC ACTION OF EXPIRED AIR.

Experiments of Haldane and Smith [13] fail to support Brown-Séquard's hypothesis that expired air contains a special organic poison. The authors draw the following conclusions from experiments on human beings:

(1) The immediate danger from breathing air highly vitiated by respiration arises entirely from the excess of carbonic anhydride and deficiency of oxygen, and not from any special poison. Experiments on animals, consisting of injecting the products of respiration into them caused no more ill-effect than the injection of distilled water.

(2) Excess of carbonic acid rather than deficiency of oxygen is the more potent cause of hyperpnœa and headache.

HYDROCYANIC ACID.

Since hydrocyanic acid is oxidized to oxamide by hydrogen peroxide, experiments were made by P. Krohl [14] to see if the latter substance could be employed as an antidote in the case of hydrocyanic acid poisoning. These experiments were successful, and the acid, in larger quantity than the fatal dose, was administered to dogs and cats, and its effects stayed by means of hydrogen peroxide. The experiment could be made daily for weeks together without permanently injuring the animal. Moreover, the acid could not be detected in the urine after application of hydrogen peroxide, whereas it is present in ordinary cases of hydrocyanic acid poisoning.

POISONING BY HYDROGEN SULPHIDE.

Lehmann [15] has established by an elaborate investigation, that the inhalation of 0.07 per cent. to 0.08 per cent. hydrogen sulphide in the atmosphere produces in man, in the course of a few hours, very dangerous symptoms; the presence of 0.1 to 0.15 per cent. causing death quite rapidly. 0.015 per cent. in the air can be inhaled for some hours without detriment; but more than 0.02 per cent. produces injurious effects. The system cannot be made to tolerate this gas; on the contrary, it becomes more sensitive upon repeated inhalations. Uschinsky [16] could not find any evidence that the gas acts as a hypnotic, as Schulz states.

Cholera Precautions in Hamburg. — In order to take all precautions against the introduction of cholera to the city, the Hamburg authorities have ordered that only Russian emigrants who have cabin tickets to America will be allowed entry to their territory.

Reports of Societies.

THE ASSOCIATION OF AMERICAN ANATOMISTS.

MEETING at Princeton, N. J., December 27–29, 1892, D. S. LAMB, M.D., Secretary.

DR. F. H. GERRISH read a paper on

THE NEED OF AGREEMENT ON THE LIMITS OF THE ABDOMINAL REGIONS, AND A PROPOSITION FOR A NEW METHOD OF DIVISION.[1]

DR. E. A. BALLOCH read a paper on

DELIMITATION OF ABDOMINAL REGIONS.[2]

DR. THOMAS DWIGHT, of the Harvard Medical School, said that he was inclined to agree with Dr. Balloch rather than with Dr. Gerrish. While he thought the latter's method of dividing the abdomen the best that he knew, it was by no means perfect. The lowest part of the cartilage of the tenth rib cannot in all cases be certainly recognized, nor is it always in the same place. The position of the lines must be influenced by sexual and individual peculiarities, to say nothing of the effect of various degrees of distention of the abdomen. It is needless to say that the regions of the abdomen have no morphological significance, and in surgical practice the situation of a tumor is usually described by means of measurements from fixed points.

Dr. Dwight is in the habit of teaching that it is convenient to retain the customary names of these regions, but that it should be recognized that they are to be used vaguely, and that it is useless to pretend to define by sharp lines where one region ends and another begins.[3]

DR. GEO. A. PIERSOL, University of Pennsylvania: While appreciating fully the force of Dr. Dwight's remarks, yet the fact remains that the nine conventional divisions will continue to find place in our text-books. It is, therefore, very desirable that uniformity in the arbitrary boundaries adopted should prevail. The lines advocated by Dr. Gerrish offer the advantage of being largely determined by accessible skeletal points. Almost identical boundaries have been adopted by Joessel, who, however, assumes as the vertical lines perpendiculars erected from the ilio-pectineal eminences.

DR. CARL HEITZMANN, New York City: It seems to me that we will never come to an agreement in an open meeting, the more so, since the views held by German anatomists have entirely been neglected. Some take the nipples as starting points, joining the spinæ ilii anteriores. The best division seems to me that adopted by Hyrtl and others. He starts from the sterno-clavicular articulations, sending lines to the spinæ ilii anteriores. Then he joins transversely the lowest borders of the tenth ribs and both spinæ ilii; the region outlined by the lower borders of the ribs and the processus zyphoideus on the one hand, and the transverse line between the tenth ribs, he terms *epigastrium*; the region between the two transverse lines (tenth ribs and both spinæ ilii), he terms *mesogastrium*; and that between the transverse line uniting both spinæ and the upper border of the iliac bones, *hypogastrium*. The mesogastrium is subdivided by a horizontal line starting from the navel into a regio supra-umbilicalis and a regio infra-umbilicalis; the hypogastrium, by a vertical line into the mesial regio pubis and the lateral regio inguinalis. In my judgment, the papers should be referred to the Committee on Nomenclature, which, in due time, may report to the Association for final decision.

DR. D. S. LAMB, Army Medical Museum, Washington: I am inclined to favor the proposition of Dr. Balloch, to divide the abdomen into quadrants by a median sagittal plane and a horizontal umbilical plane. I do not see how any careful person can make a mistake concerning these planes. They are uniform for all subjects; assuming, as I do, that the position of the umbilicus, for all clinical purposes, is sufficiently uniform in its relations to neighboring parts. Besides the horizontal plane it corresponds very closely to the uppermost level of the iliac crest, the body of the fourth lumbar vertebræ and the aortic bifurcation. The only important viscera below this plane are the intestines and pelvic organs. The position of a point stated to be three inches to the right of the median line and three inches above the umbilical line in an adult, lying on his back, would be understood by every one, and be easily marked on a chart or on the body of another subject. If anatomists would state, for instance, that the pylorus is found on the average to be so far above and so far to the right of these respective lines, there would be no doubt in the mind of the reader as to the precise place indicated.

[1] See page 10 of the Journal.
[2] See page 13 of the Journal.
[3] For the views of some English anatomists as well as for a further statement of Dr. Dwight's opinion, the reader is referred to the last Report on Anatomy in the Journal of May 25, 1893.

AMERICAN MEDICAL ASSOCIATION.

FORTY-FOURTH ANNUAL MEETING, MILWAUKEE, WIS., JUNE 6–9, 1893.

(Concluded from Vol. cxviii, No. 26, page 650.)

THURSDAY, JUNE 8TH (CONTINUED).

The next thing in order was the Report of the Nominating Committee, which was read by the Chairman, DR. TRUAX, of New York. The committee recommended for

President, James F. Hibberd, of Richmond, Ind. First Vice-President, John A. Wyeth, of New York. Second Vice-President, I. N. Love, of St. Louis, Mo. Fourth Vice-President, U. O. B. Wingate, of Milwaukee, Wis. Treasurer, Richard J. Dunglison, of Philadelphia, Pa. Secretary, William B. Atkinson, of Philadelphia, Pa. Assistant Secretary, H. B. Ellis, San Francisco, Cal. Librarian, Geo. W. Webster, of Chicago, Ill. Editor Association Journal, J. C. Culbertson, Chicago, Ill. Trustees, J. B. Hamilton, Chicago; E. E. Montgomery, Philadelphia, Pa.; E. Fletcher Ingals, Chicago; L. S. McMurtry, of Louisville, Ky. Members of Judicial Council, X. C. Scott, Ohio; G. W. Stone, United States Marine-Hospital Service; J. T. Jelks, Hot Springs, Ark.; J. H. Murphy, of Minnesota; J. McFadden Gaston, Atlanta, Ga.; T. A. Foster, Maine; I. N. Quimby, New Jersey. Address on Medicine, C. H. Hughes, St. Louis, Mo. Address on Surgery, Ernest LaPlace, Philadelphia, Pa. Address on State Medicine, Geo. H. Rohe, Catonsville, Md. Place of meeting, San Francisco, Cal. Chairman of Committee of Arrangements, R. H. Plummer.

The nominating committee also recommended that the Secretary be paid an annual salary of $500.

It was moved and seconded that the report be adopted.

DR. ROHE moved to substitute Baltimore as the next place of meeting; but after ringing and enthusiastic speeches made by a member from California, DUDLEY S. REYNOLDS, of Louisville; LEARTUS CONNER, of Detroit; H. A. HARE, of Philadelphia; H. O. MARCY, of Boston; N. S. DAVIS, of Chicago, and F. W. MCRAE, of Atlanta, the report was adopted as read.

The Report of the Committee on President's Address was then read by DR. HIBBERD, indorsing in the form of resolutions, all the suggestions contained therein. On motion, the report was adopted.

On motion of SECRETARY ATKINSON, several Canadian physicians were made members by invitation.

DR. JOHN B. ROBERTS, of Philadelphia, offered a resolution to the effect that all amendments now on the calendar, be postponed until the meeting next year, to be taken up on the second day of the Association meeting in general session. Carried.

FRIDAY, JUNE 9TH.— GENERAL SESSION.

The Association was called to order by PRESIDENT MCGUIRE at 11 A. M.

DR. WALTER WYMAN, of Washington, D. C., read the Address on State Medicine. He selected for his subject "Extinction of Contagious Diseases." He said the history of the world shows that whole races of men and other animals have become extinct. Why should not races of microbes become extinct, and certain diseases that once ravished the earth in epidemic form have so lost their inherent strength or have been so controlled in the latter part of the nineteenth century as to warrant the belief that their histories are closed, or fast closing.

With regard to yellow fever, the great period of its history was from 1793 to 1805. Formerly it was of common occurrence in Europe, the ports of Spain in particular, suffering severely between 1801 and 1825, but there has been no disastrous epidemic of this disease in Europe since that of Lisbon in 1857, thirty-six years ago. Its earlier history in this country includes invasion, not only of the South, but of ports as far North as Pennsylvania, New Jersey, New York and even New Hampshire. But to-day, though constant vigilance against its introduction is necessary, it has practically vanished from the ports of the United States.

He said since the discovery of vaccination by Jenner in 1796, small-pox, though still a stubborn foe, no longer devastated without restraint. It is now simply a matter of choice whether one shall be made absolutely proof against this disease, and the good effects of a compulsory law regarding vaccination were seen in the statistics of Prussia, in which country, for six years prior to the enforcement of vaccination, the deaths from small-pox averaged 85 per 100,000 of the inhabitants, while from 1875 to 1886, after the law came into force, the yearly average was but two per 100,000.

Typhus fever flourished to-day in certain parts of Mexico, and was occasionally reported from the Old World. It was always a menace where large numbers of people were crowded together with unsanitary surroundings. But it has no permanent lodgment in the United States, and the energetic and successful measures instituted by the Board of Health of New York during the past winter to suppress this disease, although it appeared in a section of the city more densely populated than that of any other city in the world, were a striking example of what may be accomplished by proper law, energetic execution and scientific disinfection.

With regard to cholera, which was still an ever threatening menace, the history of the past few years had demonstrated most clearly its relation to filth and to contaminated food and water, both of which conditions required only the peculiar energy and love of cleanliness characteristic of the Anglo Saxon race. In recent years the superior sanitation of England, and the more perfect quarantine surveillance of the United States, had served to protect these two nations from this exotic disease. One possible agency in the elimination of these diseases, still young as a science, but not without promise, was protective inoculation. Whatever opinion may be held of Freire's inoculations for yellow fever, and Kitasato's and Haffkine's inoculations for cholera, the investigations of these and other bacteriologists in this particular field, warranted the hope that results would be attained equal in efficiency to vaccination for variola.

The permanent Secretary read an invitation from the American Pharmaceutical Association to send delegates to their meeting at Chicago, August 14, 1893.

The permanent Secretary presented from the General Business Committee the following resolutions, which were adopted by the said Committee, and were submitted for the approval of the Association:

Resolved. That no paper shall be read by title in any Section which is not actually in the hands of the officers of the Section, and that the Secretary of the Association be instructed to communicate this action to each Section.

Resolved. That the General Business Committee hereby request the officers of Sections to communicate to this Business Committee any general resolutions passed relating to the conduct of the Sections.

Resolved. That we recommend that the Treasurer and Committee of Arrangements adopt measures to secure, by courteous circular letters, as large a registration of members as possible by mail three or four weeks before each annual meeting. Also that one month after the annual meeting, each member who has not paid his annual dues, be sent a notice that dues have not been paid, and that he be requested to remit the same; further, that similar notice be sent at each of the two succeeding months to those who do not remit; and that those who still fail to remit, be drawn on at sight at the beginning of the next month, having been notified that they would be thus drawn on at the time specified.

Unanimously adopted.

From the Section of Materia Medica and Pharmacy a resolution was offered and adopted to the effect that the American Medical Association recommend that the next edition of the "United States Pharmacopœia" soon to be issued, be at once practically adopted by physicians in prescribing and pharmacists in compounding. It also advises the general adoption by physicians and pharmacists of the "National Formulary," issued by the American Pharmaceutical Association, and that the teaching medical and pharmaceutical colleges adopt these works as text-books.

DR. J. E. BOYLAN offered the following amendment to By-law Number II, relating to Sections. The first clause of paragraph 5 shall be amended to read:

"It shall be the duty of every member of the Association who proposes to present a paper or report to any one of the Sections, to forward either the paper or a title indicative of its contents and its length, to the Secretary of said Section, at least one month before the annual meeting at which the paper or report is to be read." Adopted.

A communication from Dr. J. M. Toner, of the Committee on Jenner Centennial, reported progress, and asked permission to fill a vacancy in the Committee owing to the death of Dr. T. F. Wood, of North Carolina.

The report was received and permission granted.

The President announced delegates to the Eleventh International Medical Congress at Rome, and also a delegate to the American Pharmaceutical Association in the person of Dr. Frank Woodbury, of Philadelphia.

On motion the President and permanent Secretary were granted authority to appoint other delegates, if deemed desirable.

The permanent Secretary read the following as officers of Sections.

Surgery and Anatomy: Chairman, J. B. Roberts, Philadelphia; Secretary, F. W. McRae, Atlanta, Ga.

Practice of Medicine: Chairman, H. A. Hare, Philadelphia; Secretary, W. H. Washburn, Milwaukee.

Obstetrics and Diseases of Women: Chairman, Joseph Eastman, Indianapolis; Secretary, George I. McKelway, Philadelphia.

Neurology and Medical Jurisprudence: Chairman, J. G. Kiernan, Chicago; Secretary, Frank P. Norbury, Jacksonville, Ill.

Ophthalmology: Chairman, A. R. Baker, Cleveland, O.; Secretary, L. H. Taylor, Wilkesbarre, Pa.

Laryngology and Otology; Chairman, E. Fletcher Ingals, Chicago; Secretary, J. F. Fulton, St. Paul.

Materia Medica and Pharmacy: Chairman, Frank Woodbury, Philadelphia; Secretary, F. E. Stewart, Watkins, N. Y.

Diseases of Children: Chairman, W. S. Christopher, Chicago; Secretary, Frank A. Churchill, Chicago.

State Medicine: Chairman, Geo. W. Stoner, United States Marine-Hospital Service; Secretary, C. H. Sheppard, Brooklyn.

Dermatology and Syphilography: Chairman, A. H. Ohmann-Dumesnil, St. Louis; Secretary, L. F. Frank, Milwaukee.

Physiology and Dietetics: Chairman, I. N. Love, St. Louis; Secretary, E. Cutter, New York.

Oral and Dental Surgery: Chairman, W. H. Fletcher, Cincinnati; Secretary, E. S. Talbot, Chicago.

The President appointed as the Committee to confer with the American Public Health Association, Drs. U. O. B. Wingate, of Milwaukee; Jerome Cochran, of Alabama, and J. H. Parkinson, of California.

Dr. Robert Reyburn, of Washington, D. C., offered resolutions of thanks, which were unanimously adopted.

Dr. James T. Jelks resigned from the Judicial Council because he was already a member of the General Business Committee.

On motion the resignation was accepted.

President McGuire, in retiring, thanked the Association for the kind treatment extended him and to the permanent Secretary and others who had aided him so efficiently. He then introduced Dr. J. F. Hibberd, of Richmond, Ind., the President-elect, who assumed the chair in a felicitious manner, asking all to go to California next year and in every way to aid in building up the Association.

There being no further business, the Association adjourned to meet in San Francisco, Cal., on the first Tuesday in May, 1894.

Recent Literature.

Human Monstrosities. By BARTON COOKE HIRST, M.D., Professor of Obstetrics in the University of Pennsylvania, and GEORGE A. PIERSOL, M.D., Professor of Histology and Embryology in the University of Pennsylvania. Part IV. Philadelphia: Lea Brothers & Co. 1893.

A notice of the first three parts of this superb work appeared in the number of this JOURNAL for January 12, 1893, to which the reader is referred for a statement of the general plan, purposes and scope of this valuable addition to medical literature.

Part IV is fully illustrated with forty-six wood-cuts and ten photographic reproductions. The first thirty-three pages of text are devoted to the continued description of composite monsters. Of the dicephali, perhaps the most interesting are the Tocci boys, born in 1877, and still living in good health. Of the pygopagi, an interesting account is given of the Hungarian sisters, Helen and Judith, who lived to be twenty-two years of age, and also of the North Carolina and the Bohemian twins.

The most famous example of the xiphopagi is that of the Siamese twins, who are interestingly described: the text contains a photograph of the external appearances from a cast in the Mütter museum, and a plate (by Pancoast) of the internal anatomy. There is also an account of four operations for the separation of this class of monsters. Eighteen pages are devoted to double parasitic monsters, and there is a brief notice of triple monsters, of which only two or three authentic cases are recorded. The work is concluded with an adequate index, and a valuable bibliography referring to works on teratology, monographs, and journal articles.

As a whole the work is a great credit to the learning and industry of its authors, and a great credit, too, to American medical literature. The English-speaking profession are under obligation to the authors for placing within their reach in the vernacular the literature of this most interesting subject. C. M. G.

Modern Gynæcology: A Treatise on Diseases of Women. By CHARLES H. BUSHONG, M.D. New York: E. B. Treat. 1893.

The present volume compares favorably with many recent publications on the same subject, and is a suggestive and safe book to put into the hands of the student and general practitioner. The specialist will find it too elementary. It is on the whole well written, and covers the ground of medical and minor gynæcology pretty thoroughly. Many of the illustrations are old, and some of them crude. While there are many minor points on which we would not agree with the author yet in the main the teaching is sound.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 6, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ORGANIC EXTRACTS: THE NEW DEPARTURE IN NEUROLOGICAL THERAPEUTICS.

IT was the privilege of some of the physicians of Boston to listen, some months ago, to a fresh and vigorous paper on the above subject, by Prof. C. L. Dana, of New York, well known as a progressive and independent student and teacher of neurology; and it is to this paper, since then published in our JOURNAL [1] that we wish to call the attention of our readers, as being a good introduction to an important subject.

Dr. Dana begins by pointing out how the last few decades have been for the neurologist a time so richly fruitful of refinements and discoveries in nosology and anatomical detail that his time and thought have been given but grudgingly to the study of the causes of disease and the art of healing.

But at last, through the influence of modern bacteriology and pathology, the tide is turning or has turned. No neurologist, as he rightly judges, can now afford to be ignorant of the doctrines of toxæmia, and phagocytosis, and sepsis, or of the vast changes which have come over the old conceptions of inflammation and degeneration, nor of the therapeutic suggestions to which these new views are leading.

Whether the fascinating deductions of Metschnikoff are wholly right or not, it is fair to conclude that the active cause of cellular degeneration and death is a poison, and that our duty as physicians is to learn how to assist the body in its struggle to destroy or arrest this poison, since we can do so little to repair its ravages. We have gone far enough for the present, in the observation of the dead cell under the microscope; let us devote ourselves more to getting rid of the poison that kills it, and be "humoralists" again for a time. Death from acute meningitis and encephalitis and myelitis is death from poisoning; and even the chronic inflammations and degenerations, and some of the chronic neuroses [2] are of similar origin.

How to arrest these causes of disease we are as yet almost wholly ignorant, but we may at least join hands with those who are studying "the applications of the ferments immunizing serum, extracts of normal tissues and organs, and antitoxines, from whatever source we can obtain them."

Dr. Dana has been using, since July, 1892, various animal extracts of the thyroid gland, and of the brain tissue; as well as the rabic virus and Hunter's modification B of tuberculin; and the summary of his observations is as follows:

Locomotor ataxia (brain extract), eight cases (six treatment complete, two discontinued). Four improved, two not improved.
Bulbar paralysis (brain extract), one case. Cured.
Progressive muscular atrophy in late stages (brain extract), three cases. Not improved.
Epilepsy (brain extract, rabic virus and testicular extract), five cases. Three improved, two not improved.
Two other cases whose course was known to me were improved.
Paralysis agitans (brain extract), one case. Not improved.
Tubercular tumor of brain (Hunter's modification B of tuberculin), one case. Not improved.
Basedow's disease (thyroid extract), one case. Symptoms increased.
Dementia (thyroid extract), one case. Improved.

The case of bulbar paralysis is given at length, and is highly interesting and important.

With this brief summary we must leave Dr. Dana's refreshing and straightforward paper, for the sake of discussing some aspects of the subject in a general way, and with reference, also, to a few other communications. We are heartily with him in his hopeful striving, and agree with him that "there is no more reason to doubt that there should be therapeutical properties in extracts obtained from animal organs than that there should be such from vegetable organs."

Indeed, it is possible to go much further than this. We have had efficient pepsine and pancreatine for many years; and the cure of myxœdema by thyroid extracts, even such as have passed through the crucible of the stomach and the filter of the intestinal walls, is an event to be counted upon (*mirabile dictu!*) as certain.

But while we wish well to the new therapeutics, and admit, in general, the doctrines on which it is based, we feel it a duty to assert that the facts do not seem to us to justify any such extravagant statements as those made by some of the advocates of the organic extracts.[3] Indeed, this is one of the cases where it is the duty of every considerative man to distrust even his own power of observation, and, still more, his own power of referring what he sees to its true cause. The time has not even yet come when we can say with safety that now we will wipe off the slate and begin to

[1] Modern Pathology and the Pathology of Nervous Diseases, with some Therapeutic Deductions and Experiments with Organic Extracts. Boston Medical and Surgical Journal, May 18, 1893.

[2] The recent Report in Neurology of the Johns Hopkins Hospital contains an elaborate contribution to the germ theory of chorea by Henry J. Berkeley; and in our issue of January 5, 1893, we collated some of the new views in this line as to the pathogeny of epilepsy.

[3] See the British Medical Journal from June 3d and 10th of this year, for Professor Brown-Séquard's most recent utterances on this subject.

count our observations as of permanent value. We must not forget that chapter in the long history of error, which deals with the suspension treatment of tabes. There is no marvel claimed for testiculine which cannot be fully paralleled by results clearly referable to hypnotism, and — take it as you will — the remarkable investigations of late years into this branch of psychology have shown that mental influences have an enormous power of removing symptoms of disease and changing nutritive conditions, and that it is extraordinarily difficult to be sure that we have eliminated them. It is, moreover, by no means those mental influences that appeal most obviously to the intelligence or to the imagination that exert the most effect. The powerful phantom of "suggestion" often stands behind the physician's chair, invisible alike to him and to his patient, though both of them believe that they have, Faust-like, discovered and used the spells which would have forced him to materialize had he been present.

It is true that the wonderful history of myxœdema and its treatment should make us ready for new developments in the same line, and anything that is equally attested will find itself equally accepted; but there is as yet neither experiment nor observation which place the results which are claimed to follow injections of testiculine and cerebrine on anything like the same plane.

Myxœdema we can cause and we can cure, with practical certainty, by removing or supplying the thyroid secretion. Can we cause and cure tabes or neurasthenia or arterio-sclerosis [4] with similar certainty, by removing the testes or by injections of spermatic extract?

Most of the signs of improvement have been such as were furnished by the patient's own feelings. It is said that many "cures" have been made; but in view of the fact that many failures to cure are likewise on record it is permissible to question whether the disease itself has been really cured at all. At any rate, this result does not occur as frequently as it does in myxœdema.

"Ameliorations" do not count for much, with a new remedy.

Castration causes a remarkable train of results, and it would be a reasonable and a highly interesting experiment to see if these could not be prevented or cured by testiculine, but neither the ox nor the eunuch is neurasthenic or tabetic.

It may eventually be proved by accurate physiological experimentation that testiculine does exert some powerful action on the nervous system. These proofs would be highly welcome, but they are not yet forthcoming.

It is significant that Professor Brown-Séquard concludes his paper by saying: "When we know how great, how various, are the morbid physical and dynamical attractions that the nervous system can produce, it is easy to understand that what it can do in one way it can also do in just the opposite way, so as to re-establish the normal state, physically and dynamically, and this may serve to explain the extreme variety of the favorable effects that may be due to certain liquids which increase considerably (as is proved) the power of the cerebro-spinal centres."

Not to speak of the uncertainty of the last assumption in this reasoning, the thought suggests itself whether, if the strengthened nervous system can work these varied effects, the argument in favor of unsuspected "suggestion" (or "expectancy," if the term be preferred), which is well-known to strengthen the nervous system, is not reinforced by these considerations.

This feeling had already grown up in our mind when we received a pamphlet by an Italian physician, Massalongo, Docent at the University of Padua, devoted to sustaining this view. Its title, which we give below,[5] sufficiently indicates the character of its contents.

We do not definitely take this ground,[6] for it would be a great misfortune if any investigation of value should be checked, and any opportunity omitted for increasing our therapeutic resources. There is nothing more improbable in the idea that disease should be cured by one organic fluid than that it should be caused by another; but it is a question of evidence in each case whether or not this is true, and a large amount of evidence is required to establish so new a proposition.

The study of toxines and antitoxines has opened men's minds amazingly. The life of a healthy man, well cared for and protected, runs on so smoothly that he does not dream how often he passes by the brink of lighter or severer self-intoxications; nor that it is his organic secretions that, for the most part, render him liable to these dangers and provide safeguards against them. Special conditions of the blood are unquestionably correlated, not only to the health of the tissues, but to the structure of the body as a whole. The lack of a few grains a day of thyroid juice makes the child grow up a cretin; the lack of the testis makes the bull-calf grow up an ox. It is said to be a special diet alone that is needed to make the queen bee develop from the worker.

We should gladly welcome the discovery of diets or organic ferments that can neutralize the causes of disease, but the pendulum ought not to be allowed to swing so fast and far that its inevitable return will occur with destructive force.

We are glad to hear of Dr. Dana's results, and glad to hear of the experiments going on in our own city. But some of the reports would almost make it appear as if we might hope to cure everything with anything, so long as the remedy bore the magic name of "organic." We do not believe that this will prove to be the case.

MEDICAL NOTES.

The Drought in Europe. — Both England and parts of the Continent have suffered much from lack of rain-fall. In many places no rain of any consequence has fallen for over three months; many crops are ruined; much live-stock has been killed on account of the lack of food for them; and the water-supply of many towns has either given out or has been very much reduced. What water there is has become bad to drink, and in some places mild epidemics of typhoid have appeared.

Suicides in France. — The official report of suicides in France for the year 1891 shows that the total number was 8,180, or 21 per 100,000 inhabitants. Of this number 78 per cent. were males. The methods adopted appeared to differ much according to the sex. Hanging is a favorite method with men, more than half having got rid of themselves in this way, whereas drowning is chosen relatively more by women. The greatest relative difference was by firearms, which were chosen by 780 men and only 52 women, whereas poison attracted only 79 men and 104 women.

NEW ENGLAND.

Appropriations for Public Institutions. — Among the appropriations in the Loan Bill passed by the Boston City Government last week were the following: Boston City Hospital, for new buildings $400,000; Long Island Institutions and the Lunatic Hospital, each $100,000.

A Boylston Medical Prize for 1893 has been awarded to Drs. Wm. E. Hughes and Wm. S. Carter, of Philadelphia, for an essay entitled, "A Clinical and Experimental Study of Uræmia."

Massachusetts Medico-Legal Society. — At the annual meeting of this Society, June 13, 1893, the following officers were elected for the ensuing year: President, Dr. Z. B. Adams; Vice-President, Dr. S. W. Abbott; Recording Secretary, Dr. F. W. Draper; Corresponding Secretary, Dr. B. H. Hartwell; Treasurer, Dr. A. E. Paine.

NEW YORK.

Small-Pox. — On June 26th the State Board of Health was notified of the existence of fourteen cases of small-pox at Yonkers, on the Hudson. Six of the cases had their origin in the house where the first case reported was quarantined.

Revoked Charters. — The Board of Regents of the University of the State of New York have recently revoked the charters of the "College of Midwifery of the City of New York," and the "College of Massage," two institutions under the same management.

"Odi Persicos." — On June 24th, Goolam Kader, a notorious Arabian quack oculist, was held for trial in Special Session on a charge made by the Medical Society of the County of New York, of practising medicine without a license; bail being fixed at $500. A few days previously he had opened an office and inserted glowing advertisements in a number of newspapers, including several published in French, German and Italian. One of these attracted the attention of Dr. Ferdinand C. Valentine, an accomplished linguist, who, as the editor of *Medical Abstracts*, is in constant receipt of all the foreign medical journals; and he at once recognized the name as that of a quack who on account of his outrageous practises had been prosecuted in Genoa, Brussels, Cologne, Berlin and many other Continental cities. Dr. Valentine found from his reading that his favorite operation was that for cataract, and that in consequence of his so-called "cures" hundreds of cases of total blindness had resulted. He at once reported the fact of the man's establishing himself in New York to the County Medical Society, and the career of this dangerous charlatan here was quickly cut short. The other American cities will now have to be on the lookout for him.

Overcrowded Insane Asylums. — The Grand Jury having made some severe strictures upon the overcrowded and generally unsatisfactory conditions of the city asylums for the insane on Ward's and Blackwell's Island, the Mayor wrote a letter to the Commissioners of Charities and Correction, calling attention to the presentment and inquiring what disposition had been made of $500,000 which was appropriated in December last for the repair of old buildings and the erection of new ones, on Ward's Island and at the city's farm at Central Islip, Long Island. In reply, the Commissioners state that the new buildings on Ward's Island are progressing rapidly, that four new buildings at Central Islip will be ready for occupancy within ten days, and that all the new buildings in both locations will be completed by October 1st. They also report that the number of insane patients cared for by the city amounted on June 1st to 5,939, an increase of 489 since the first of January last, and that they will need another $500,000 to effectually relieve the overcrowding of the asylums and to provide for the natural increase of the insane.

Underpaid Assistants and Nurses. — Some two months ago Mrs. Martha Adair, a patient ninety-four years of age in the Brooklyn City Asylum for the insane at Flatbush, died under circumstances which led the coroner's jury which investigated the case to censure the asylum authorities. Later the Grand Jury indicted the superintendent Dr. Sylvester Phillips, and Ellen Reilly, the nurse who had charge of the patient, for manslaughter in the first degree on the ground of gross negligence; but they were both retained in office by the Commissioners of Charities and Correction. Now the Grand Jury for the June term has made a presentment in which it charges the superintendent with gross neglect of duty and finds that the general management of the institution by him to have been extremely faulty and unsatisfactory. It also charges the nurse, Ellen Reilly, with gross neglect of duty and incompetence, and recommends the immediate dismissal of both. It finds, furthermore, that the rates of pay for the assistant physicians at the asylum are not sufficient to obtain the necessary ability,

and recommends that the rate of compensation be fixed at from $800 to $1,500 per annum, together with the customary allowances of board and lodging. Among the other recommendations made by the Grand Jury are the following: That the pay of male nurses be from $20 to $40 a month, and of female nurses, from $20 to $30 a month; that quarters sufficient to accommodate the requisite number of nurses be erected; that such changes be made in the law as shall make the Charities Commissioners of Brooklyn solely responsible for the administration of the asylum; and that at least one of the Commissioners shall be a competent physician.

Miscellany.

IMPROVEMENTS IN THE MEDICAL DEPARTMENT OF THE ARMY.

SURGEON-GENERAL STERNBERG has inaugurated the establishment of two new features in the medical department of the army. The first is to be known as the Army Medical School, and is to consist of a course of four months' duration given in the Army Medical Museum for the benefit of newly appointed medical officers. The general order providing for the school is as follows:

By direction of the Secretary of War, upon the recommendation of the Surgeon General of the Army, an Army Medical School will be established in the city of Washington for the purpose of instructing approved candidates for admission to the Medical Corps of the Army in their duties as medical officers. The course of instruction will be for four months and will be given annually at the Army Medical Museum in Washington city, commencing on November 1st. Four professors will be elected from among the senior medical officers of the army stationed in or near the city of Washington, and as many associate professors as may be required to give practical laboratory instruction in the methods of sanitary analyses, microscopical technique, clinical microscopy, bacteriology, urine analysis, etc.

The faculty of the Army Medical School will consist of: (1) A president of the faculty, who shall be responsible for the discipline of the school, and who will deliver a course of lectures upon the duties of medical officers in war and peace (including property responsibility, examination of recruits, certificates of disability, reports, rights and privileges, customs of service, etc.). (2) A professor of military surgery (including the care and transportation of wounded). (3) A professor of military hygiene (including practical instruction in the examination of air, water, food and clothing from a sanitary point of view). (4) A professor of clinical and sanitary microscopy (including bacteriology and urinology).

A new system of assignments of medical officers is also to be established. It has been the custom to detail older surgeons for duty in large cities, where they sometimes remained for some years. Hereafter surgeons with the rank of captain will be detailed for one year; so that opportunity will be given for the officer to become familiar with the work done in hospitals and an opportunity given for attending lectures and meetings of medical societies. The details will be made in Boston, New York, Philadelphia, Baltimore, Chicago, St. Louis and San Francisco. The senior medical officers who have heretofore been stationed in several of these cities as attending surgeons will be required to perform the more responsible duties of post surgeons at the larger military posts, where, as a rule, one or more younger officers will also be stationed as assistants. The policy will not only give the younger men of the medical corps better opportunities for professional advancement, but it will give them the benefit of the experience of the seniors and of their necessary instructions and discipline which so often in the past they failed to receive.

THE CAUSE OF DEATH IN BURNS.

HOCK in the *Wiener klinische Wochenschrift*, No. 17, describes a series of experiments in 32 cases of extensive burns during life, of which number one-half finally died. A gradual increase in the density of the blood always occurred, the highest point being reached in about eight hours after the injury, and in cases which recovered returning to normal in about two days. The author concludes that this is due to the inability of the blood to retain its plasma, such a condition not accompanying any other disease. As to the primary cause, he attributes the change to the alteration which has taken place in the red blood-cells, and thinks a connection exists between these two changes as produced by overheating of the blood to 40° to 58° C. The blood thus damaged has also been shown to possess toxic properties apart from the resorption of poisonous material which takes place on the surface of the wound. These factors tend to explain the symptoms analogous to anæmia without any loss of hæmoglobin being perceptible. There is also danger in the formation of emboli, thrombi, and parenchymatous degenerations. As to treatment, the author believes that subcutaneous injections of salt are useless. Intravenous injections show very good though temporary results. The proposal to remove the exudations surgically is treated lightly, as being impracticable or unnecessary.

THE TREATMENT OF MALIGNANT TUMORS BY INOCULATIONS OF ERYSIPELAS.

DR. W. B. COLEY records a series of cases in which an attack of erysipelas coming on either accidentally or from inoculation appeared to produce an antagonistic effect to malignant disease.[1] Some of these cases occurred before the publication of Fehleisen's experiments in Germany; most of them are of recent date. Injections of pure culture of the streptococcus of erysipelas were injected into the tumor substance. Erysipelas thus artificially produced is not a dangerous condition. In many cases the malignant growth appeared to be checked, and sometimes entirely disappeared. If a recurrence showed itself, another inoculation was made, and in some cases several. Occasionally it was not possible to produce erysipelas by inoculating. The author refers to the recent experiments of Spronck, who injected the toxic products of the streptococcus of erysipelas at a point distant from the seat of the malignant disease, with great improvement in cases of sarcoma and but little effect in cases of carcinoma. The author used repeated injections of pure fluid culture, generally deeply into the tumors themselves. A reaction, with a temperature of 104° (lasting for one or two days) generally followed in cases where erysipelas was not produced. The effect

[1] American Journal of Medical Sciences, May.

upon the malignant growth is more brilliant and permanent where an attack of true erysipelas has resulted. Very rarely is an abscess formed from the injection; when there is, the author believes that a mixed infection is present. He concludes that the curative effect of erysipelas upon malignant tumors is an established fact. The action upon sarcoma is more powerful than upon carcinoma, in about the ratio of three to one. The treatment of inoperable tumors by repeated inoculations of erysipelas is both practicable and not attended with great risk. The curative action is systemic and probably due chiefly to the toxic products of the streptococcus, which products may be isolated and used without producing erysipelas. This method should not be employed indiscriminately, until further experiments have proved its limitations. Since writing the paper, the author has used the toxic products alone in injections, and finds that the advantages of so doing are great; as the necessity for isolation is avoided, and the action of the products can be so carefully regulated that the dangerous element can be entirely eliminated.

THERAPEUTIC NOTES.

UNFAVORABLE RESULTS FROM PIPERAZINE. — Rörig[1] reports that in a certain number of cases the therapeutic use of piperazine has been followed by albuminuria, and advises caution in the use of this drug in cases where the kidneys are not sound.

CREASOTE IN PHTHISIS. — Albu[2] describes the results of treatment of pulmonary tuberculosis with creasote in the Moabite Hospital, in Berlin, for the past five years. For the last year large doses, recommended by Sommerbrodt, have been given. Creasote is without influence upon the tubercle bacilli. The author believes that its use in phthisis should only be symptomatic. For most patients it is a good expectorant; sometimes it increases the appetite and acts as a tonic; while in many cases it is useless, and in a few worse than useless.

THE TREATMENT OF DIABETES MELLITUS WITH RAW PANCREAS. — Following the analogy of the treatment of myxœdema by thyroid juice, experiments have been made in several English hospitals of feeding raw pancreas to cases of diabetes. White[3] finds that most patients take the raw pancreas quite easily. The patients gained in body weight and felt better; but in most cases the amount of sugar and quantity of urine was not diminished, although in some it was.

ACTINOMYCOSIS. — A case is reported in the *Revue Medico-Chirurgicale*, No. 7, in which a case of actinomycosis was successfully treated with iodide of potash, given in doses of twenty-five grains a day.

GALLANOL.[4] — Gallanol is a white crystalline body, of a slightly bitter taste, slightly soluble in cold, freely in hot water and in alcohol, also in ether, benzine, and in chloroform. The alkalies dissolve it, yielding a brown coloration, but without sensibly decomposing it. It is prepared by boiling tannin with anilin, treated with water acidulated with hydrochloric acid, from which it crystallizes and is purified by successive recrystallizations. It does not possess irritant properties. Cazeneuve and Rollet have used this remedy in psoriasis as an ointment, in strength from three to twenty-five per cent. It apparently has value for the treatment of eczema, catarrhal lesions of the mucous membranes, especially in the blennorrhagias of the gouty.

GREEN'S OPERATION FOR ENTROPIUM.

SALEM, June 27, 1893.

MR. EDITOR: — Of all the operations that have been devised for the relief of entropium and ingrowing eyelashes, within the last twenty-five years, that of Dr. John Green, of St. Louis, because of its simplicity and its satisfactory results, is doubtless the best.

Judging by the annual reports of eye-hospitals in this country, its merits are becoming better recognized by ophthalmic surgeons. Dr. Green's method has one advantage, especially to practitioners living in remote districts; it requires no special instruments for its performance, as a knife alone is sufficient. This operation is described in the later American treatises on the eye.

Its originator recently told me that, in many cases, he no longer excises a strip of skin above the cilia, nor does he always insert sutures. An incision is made through the conjunctiva and tarsus, about two millimetres from the lid-margin, and extending the whole length of the lid, or only as far as may seem necessary. Then, on turning up the ciliary border, the lashes will hold it well everted by means of fibres of cotton applied with collodion (United States Pharmacopœia), so as to form a support, which should be kept in place for a week or less during the healing process.

A month ago, in the case of an old woman who had suffered from tricheasis for many years, I made the incision in both lids, under cocaine, and apparently without much pain. The cilia were so far gone that it did not seem possible to keep the lid-border tilted up by means of collodion alone, so deep sutures were introduced and allowed to remain for forty-eight hours, as in the original operation, though no strip of integument was removed. The result was quite satisfactory. A not inconsiderable experience in treating this affection has caused me to prefer Dr. Green's operation to others which are more difficult to perform and the results of which are, on the whole, less gratifying.

Very respectfully,

DAVID COGGIN, M.D.

METEOROLOGICAL RECORD,

For the week ending June 24, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 3,128: under five years of age 1,329; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 641, consumption 341, diarrhœal diseases 284, acute lung diseases 279, diphtheria and croup 127, scarlet fever 66, measles 42, whooping-cough 38, typhoid fever 33, cerebro-spinal meningitis 29, erysipelas 10, malarial fever 6, typhus fever 3, small-pox 3.

From measles New York 14, Pittsburgh 9, Brooklyn 8, Chicago 4, Cleveland 2, Philadelphia, New Bedford, Quincy, Marlborough and Woburn 1 each. From whooping-cough New York 12, Chicago 8, Philadelphia 6, Brooklyn 5, Pittsburgh and Nashville 2 each, Milwaukee, Lynn and Brockton 1 each. From typhoid fever Chicago 14, Philadelphia 8, New York 6, Brooklyn and Milwaukee 2 each, Worcester 1. From cerebro-spinal meningitis New York and Chicago 10 each, Brooklyn, Washington and Cleveland 2 each, Worcester, New Bedford and Brockton 1 each. From erysipelas New York and Boston 2 each, Chicago, Brooklyn, Washington, Nashville, Springfield and Everett 1 each. From typhus fever New York 3. From small-pox New York 3.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending June 10th, the death-rate was 18.2. Deaths reported 3,597; acute diseases of the respiratory organs (London) 233, diarrhœa 148, measles 117, whooping-cough 66, diphtheria 57, scarlet fever 44, fever 21, small-pox (London 7, West Ham 3, Birmingham, Manchester and Halifax 2 each, Bristol, Leicester, Oldham and Bradford 1 each) 20.

The death-rates ranged from 9.7 in Nottingham to 24.7 in Liverpool; Birmingham 18.7, Bradford 17.9, Croydon 11.5, Hull 18.5, Leeds 20.1, London 18.1, Manchester 21.0, Newcastle-on-Tyne 17.7, Portsmouth 13.1, Sheffield 16.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 24, 1893, TO JUNE 30, 1893.

By direction of the President, CAPTAIN MARCUS E. TAYLOR, assistant surgeon, will report in person to the president of the Army Retiring Board at Fort Logan, Colorado, when required by the Board for examination by it.

FIRST-LIEUT. FRANK T. MERIWETHER, assistant surgeon, U. S. A., is relieved from duty at Madison Barracks, N. Y., and ordered to Fort Logan, Colorado, for duty.

CAPTAIN LOUIS A. LAGARDE, assistant surgeon, will, in addition to his present duties in connection with the World's Columbian Exposition, furnish the necessary medical attendance for the officers and enlisted men of the Army on duty at the Exposition grounds.

CAPTAIN WILLIAM C. SHANNON, assistant surgeon, in addition to his duties in the office of the surgeon-general, is assigned to duty as assistant to the attending surgeon in this city.

The leave of absence granted MAJOR WASHINGTON MATTHEWS, surgeon, U. S. A., is extended one month.

CAPTAIN FREEMAN V. WALKER, assistant surgeon, now on leave of absence at the Army and Navy Hospital, Hot Springs, Arkansas, will proceed at once to Fort Trumbull, Connecticut, and report in person to the commanding officer of that post for temporary duty, relieving MAJOR HENRY M. CRONKHITE, surgeon. Major Cronkhite, upon being relieved by Captain Walker, will proceed to Fort Clark, Texas, and report in person to the commanding officer for duty at that post.

FIRST-LIEUT. ALEXANDER N. STARK, assistant surgeon, is relieved from duty at Fort Monroe, Virginia, and ordered to Fort Clark, Texas, for duty, relieving CAPTAIN EDGAR A. MEARNS, assistant surgeon. Captain Mearns, upon being thus relieved, will proceed to Nogales, Arizona, and report to the senior member of the commission appointed for the location and marking of the boundary between Mexico and the United States, for duty with the commission.

AN Army Retiring Board having found MAJOR JOHN O. SKINNER, surgeon, incapacitated for active service, the extension of leave of absence on surgeon's certificate of disability, is further extended until further orders.

Leave of absence for two months, to take effect on or about July 15, 1893, is granted FIRST-LIEUT. BENJAMIN BROOKE, assistant surgeon, U. S. A.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JUNE 24, 1893.

D. M. GUITERAS, passed assistant surgeon, from Naval Hospital, Philadelphia, and to Naval Laboratory, Brooklyn, N. Y.

R. M. KENNEDY, assistant surgeon, from C. S. S. "Bache" and to examination for promotion.

GEORGE H. BARBER, passed assistant surgeon, from the U. S. S. "Miantonomoh" and to the Coast Survey.

APPOINTMENT.

DR. FRANCIS BARNES, of Cambridge, has been appointed by the Governor, Trustee of the School for Feeble-Minded, in place of DR. WILLIAM A. DUNN, resigned.

SOCIETY NOTICE.

AMERICAN NEUROLOGICAL ASSOCIATION. — At the request of the majority of the members, the Council announces that the next meeting of the Association will be held at the West End Hotel, Long Branch, N. J., on July 25th, 26th and 27th. The annual dinner will be held on the evening of the 26th.

GRAEME M. HAMMOND, *Secretary*, 58 West 45th St., N. Y.

RECENT DEATHS.

JABEZ B. LYMAN, M.D., M.M.S.S., of Salem, died June 29th, aged seventy-four years. He graduated from Amherst College in 1841, and after teaching for several years, graduated from Jefferson Medical College in 1857. He has been in Salem since 1881.

WILLIAM T. S. WARDWELL, M.D., M.M.S.S., of Roslindale, died June 24th. He was a graduate of the Harvard Medical School in 1888.

THOMAS R. DUPUIS, M.D., professor of clinical surgery and anatomy in the Medical Department of Queen's University, Kingston, Ont., died June 25th, aged sixty years.

BOOKS AND PAMPHLETS RECEIVED.

Points of Similarity Between Us and Homœopathic Physicians. By John B. Roberts, A.M., M.D. Reprint. 1893.

Catalogue of the Exhibits in the Museum of Hygiene, Medical Department of the United States Navy. Washington: Government Printing Office. 1893.

Cholera: Its Causes, Symptoms, Pathology and Treatment. By Roberts Bartholow, M.D., LL.D., Emeritus Professor of Materia Medica, General Therapeutics and Hygiene in the Jefferson Medical College of Philadelphia. Philadelphia: Lea Brothers & Co. 1893.

Lecture.

LECTURES ON THERAPEUTICS.

V. Belladonna, Etc.[1]

BY H. C. WOOD, M.D., PHILADELPHIA,
Professor of Therapeutics, University of Pennsylvania.

The subject which I have selected to study with you to-night is the mydriatics; and as time is so short I propose especially to take up belladonna as a type of these mydriatics, occupying a few moments at the end of the hour, if time suffice, with a discussion of certain other remedies of the group.

Belladonna, as you know, depends for its activity upon the presence of the alkaloid atropine. If the hundredth of a grain of atropine be taken internally the only symptoms which it produces in the average individual is a certain amount of dryness of the mouth and perhaps a little acceleration of the pulse. A sixtieth of a grain produces these symptoms to a more marked extent. A fiftieth or fortieth of a grain develops very pronounced symptoms. Now the mouth is extremely dry, the pupils are slightly dilated, the pulse is distinctly increased in its rate, and at the same time becomes hard rather than soft. After the full toxic dose of belladonna or its alkaloid the symptoms are pronounced. Intellection is affected. At first a little confusion of thought, then delirium, not stupor but delirium — a delirium in which the patient is wrapt up in his own thoughts, oblivious, indeed, unconscious of the world about him, carried away by the stream of his own ideas; a delirium in which probably the patient has hallucinations, but out of which when the delirium is passed comes no memory of these hallucinations. You may have read how the British soldiers near Jamestown in Virginia partook of the stramonium and how they became delirious, and stripped naked; in the words of the old chronicler, they "played a merry comedie." At the same time the pupil is widely dilated; respiration is usually but not always somewhat hurried; the pulse is always rapid (110, 120, 130, 140 a minute), small, corded. The bodily temperature now rises, and there comes out an efflorescence resembling the rash of scarlet fever, not so distinctly punctated as the true scarlet fever rash, a more erythematous blush; and so the hours pass by in delirium until the second stage is developed, when the forces begin to fail. The pulse continues its rapid beat, but the hardness and power is gone out of it. The bodily temperature falls. The dry skin becomes covered with sweat. The pupils keep dilated. The respiration maintains its rate, but grows more shallow. Convulsions appear or the patient sinks into quiet stupor and at last through collapse and coma, the patient passes gradually into death, all functions being obliterated with such extreme equability and so gradually that you scarcely know whether the man has died from failure of the circulation or of the respiration.

It might seem here natural, in accordance with the course I have pursued in past lectures, to say a word in regard to the diagnosis in doubtful cases of belladonna-poisoning. There is one very simple and very sure method of diagnosing poisoning by one of these mydriatics. It consists simply in withdrawing some of the patient's urine, and dropping a little of it in the eye of a brother or of a sister or of the family cat. Under these circumstances if the case be one of mydriatic poisoning there will be dilatation of the pupil. I shall pass by for the present, till I see how my time holds out, the discussion of the diagnosis between poisoning with this mydriatic and with other mydriatics and proceed immediately to the consideration of the physiological action of the remedy.

We find that belladonna produces on the whole very similar symptoms in the lower animals to those which it causes in man, with certain exceptions, however; and I note these exceptions because they bring us face to face with laws of physiological interpretation of which, unless my memory fails me, I have not spoken to you. Some of the lower animals are entirely insusceptible to the action of belladonna. The ordinary goat, so dear to the inhabitants of the outskirts of some of our great cities, rolls the stramonium cud under his tongue with especial delight; and though the infants receiving his milk may feel the effect of the stramonium, the goat himself does not. Now I believe this lack of susceptibility to be the result of inherited narcotic habit. We know perfectly well that the ordinary human individual can become accustomed to the use of a narcotic, and I believe myself that the goat of to-day loves the stramonium because the goat of yesterday was nurtured upon stramonium. It is a very curious fact that the Virginia deer eats tobacco without feeling any of its effects. I have recently seen it stated in an East India journal that certain races of monkeys will feed on the bean of nux vomica and receive no poisonous effect. It does seem as though it were possible for animals to have an acquired drug habit which could pass from individual to the race. A second exception is in regard to dilatation of the pupil, and this especially in regard to birds. Some years since I noted it as an extraordinary fact that the irides of the bird are not affected by atropine or belladonna. I came to the conclusion that there must be an anatomical difference between the iris of the bird and mammal; and I ventured the prediction that some time it would be found that the muscle fibres of the bird's iris were striated, because we know that atropia does not affect striated fibres. Some years after I had published this conjecture Bernstein and Dogiel by actual anatomical examination demonstrated that the fibres in the irides of birds are striated. They also showed that the fibres of the œsophagus of the rabbit are striated and are not affected by atropine. The cat has certain parts of its œsophagus with striated muscular fibres, other parts with non-striated fibres, and where the striated fibres come belladonna has no effect; where the non-striated fibres are belladonna paralyzes the œsophagus. Passing by these thoughts without more detail, let us study first the action of this drug upon the circulation.

Taking up the frog's heart, we find that there has been a good deal of contradiction among investigators. Some have asserted that the frog's heart has its activity increased by atropine; others that it is paralyzed by atropine. When we come to look into this discord, certain facts come out plainly. In the first place, it is absolutely certain that after toxic doses of atropine the heart is arrested in diastole, and that the heart is at this time not susceptible to the action of galvanic or other stimulant. Now, unless a drug acts through the pneumogastric nerve, it is, I think, an unquestionable fact that when it arrests the heart in diastole it acts as a paralyzant of the heart, and we have positive evidence of this fact in regard to atropine. A large dose

[1] Delivered before the Harvard Medical School Association, May 18, 1893.

of atropine brought in contact with the frog's heart paralyzes it at once, and we learn as a settled positive fact that an enormous dose of atropine paralyzes the heart muscle. The question concerning which there is doubt is as to the action of the small dose upon the frog's heart. We have the experiments of Bowditch and Luciani, which seem to indicate that the small dose stimulates the heart of the frog; also those of Ransom made upon the octopus, of Furbringer made upon the apex of the frog's heart, in which it was found a little of the atropine would start movement in the apex after it had ceased to beat. Then we have the experiments of Beyer upon the heart of the terrapin — all going to show that atropine in minute amount does stimulate the heart; and I think we must conclude that this alkaloid has some stimulant action upon the heart muscle, but that in man this stimulant influence is subordinate to action upon other parts of the system, so that we cannot use belladonna or atropine as a primary cardiac stimulant. One of the most marked phenomena of poisoning by atropine is the extreme rapidity of the pulse. This rapidity of the pulse is probably in part due to the action I have spoken of upon the heart muscle, but it is much more largely due to the influence of the drug upon the pneumogastric nerve. Bezold and Bloebaum were, I think, the first to point out that if you cut the pneumogastric nerve in the atropinized animal there is no increase in the rate of the heart. These investigators also performed an experiment which has been repeated many times since, namely, poisoned the animal, exposed the pneumogastric nerve, galvanized the nerve, and found that it had no control whatever over the heart. We know, therefore, that atropine is a paralyzant of the peripheral pneumogastric, and that the great rapidity of the heart's action under its influence is chiefly the outcome of pneumogastric paralysis; and we see now why it is that belladonna enormously increases the pulse-rate in the hound and increases it very little in the ordinary domestic rabbit. The ordinary domestic rabbit has a very feeble pneumogastric. Its pneumogastric has lost its functional activity through the years of confinement. The hound keeps down the action of the heart in the chase by its pneumogastric nerve, and so when we paralyze the pneumogastric nerve with atropine we get an enormous increase in the rate of the heart. Paralyze the pneumogastric of the rabbit, and we get only a feeble effect. I found when you took ordinary city dogs you increase the rate of the heart, but do not increase it nearly as much as you do the hound's heart. It is simply a question of the activity of the pneumogastric nerve in the life of the animal. The slight increase in the activity or power of the heart and the great increase in the rapidity of the heart in a measure account for the rise of the arterial pressure which takes place under the influence of this drug. We will find that the action of this drug upon the circulation gives us a curve something like this [drawing on the board]: a very rapid pulse, great rise of pressure and then, if the dose have been large enough, a fall. I have found, however, that if you cut the spinal cord high up and thus separate nearly the whole vaso-motor territory from the upper dominant vaso centre, that atropine will not increase the arterial pressure to any marked extent, although there is an increase of the pulse-rate. This proves that belladonna has an enormous influence upon the vaso-motor centres in the medulla, and we get here one great action of belladonna, namely, that it is a very powerful centric vaso-motor stimulant. Finally the blood-pressure falls. This final fall is the result of paralysis of the vessel walls. When in sufficient amount, atropine paralyzes all non-striated muscle fibres, and hence after atropine poisoning there is always retention of urine, because the bladder is paralyzed by the atropine in the urine lying in the viscus. The secondary fall, then, is partly the outcome of increasing cardiac weakness and partly the outcome of paralysis of the peripheral vessels, probably, also, the vaso-motor centre feels waning power following excessive primary stimulation.

I have spoken to you, I think, sufficiently at the previous lecture in regard to the action of atropine upon the respiration; I content myself now with simply saying that it acts as a powerful respiratory stimulant. Passing by the nervous system for a moment, for reasons you will appreciate later, let me call your attention to the action of this drug upon peristalsis. Under the influence of belladonna there is at first an increase in the activity of peristalsis, and then a decrease, and finally a paralysis of the intestines. The first increase in the rapidity or extent and power of peristalsis is undoubtedly connected with the action of the drug upon the splanchnic nerve. It seems to follow from the experiments of Pflüger that the splanchnic nerves are the inhibitory nerves of the intestinal tract, and it has been proved by Keuchel that galvanization of a splanchnic nerve in an atropinized animal does not affect peristalsis; in other words, the splanchnic nerves are paralyzed. The nerves of inhibition in the intestines are paralyzed by this drug; as the nerves of inhibition of the heart are paralyzed, and then as the heart muscle is paralyzed and as the bladder muscle is paralyzed, so finally are the intestinal coats paralyzed.

Now, in regard to the action of the drug upon the pupils. The action of this drug upon the pupil is that of a mydriatic. The first point I want to make is that when you put atropine in the eye of the man or animal and dilate the pupil you get an action which is local and not centric. It has been proved abundantly that you can take the humors out of an eye paralyzed with atropine and put them in a second eye and get a second dilatation; and we know, therefore, that this drug atropine dilates the pupil when it is put in the eye by acting locally upon the peripheral nerves or fibres in the eye-ball itself. Of course, we may get dilatation of the pupil by paralysis of the oculo-motor nerve or dilatation of the pupil by stimulation of the antagonist to the oculo-motor, the so-called sympathetic fibres going up with the carotid. It has been proven by several investigators that the oculo-motor nerve is paralyzed by atropine. Galvanize the oculo-motor nerve in the atropinized animal, and you get no result. We have, therefore, dilatation from oculo-motor paralysis; but I think if there be any oculist in the room he will bear me out in asserting that the dilatation of the pupil by this drug is more active than passive, that you can tear and rend exudations by it if these exudations be not too firm. It would seem, therefore, that not only does atropine paralyze the oculo-motor nerve, but that it also stimulates the antagonist of the oculo-motor nerve; this belief is further strengthened by the fact that you can get much wider dilatation from the use of atropine than you get in any ordinary oculo-motor paralysis; moreover, I have put atropine into the eye which was in the condition of oculo-motor paralysis,

and seen the drug still further dilate the pupil. I believe, therefore, that the local action of atropine in the eye is twofold, — oculo-motor paralysis, sympathetic irritation. The next point I want to make is that the action of atropine is the same, whether it be given through the circulation or whether it be put in the eye. It is a local action after all. This seems so natural as scarcely to require proving. I cannot go over the experimental evidence to-day. Suffice it to say, that a man came under my care who had been so smashed in a railroad accident that the whole temporal bone had been driven in and all the nerves going to the eye were cut. Under these circumstances I found that giving that man atropine in the leg dilated both pupils, the pupil on the uninjured side, and the pupil which was separated from the centres; and it seems to me, therefore, demonstrated that the action of atropine is a peripheral action even when the atropine is given hypodermically. You can readily see why a study of the pupil in opium-poisoning is no guide to the use of atropine. The opium contracts the pupil centrically; the atropine dilates it peripherally. There is a seeming, but not a real, antagonism in the action of the two drugs; and, therefore, in the case of narcotic poisoning when you are using atropine you are not to select the pupil as a guide to the amount of atropine which may be used. I have seen the pupil widely dilated, and atropine fail to influence the respiratory function. You use the atropine for its effect upon the respiration, and it is scarcely worth while even to look at the pupil.

And now in regard to the action of atropine upon the nervous system. In the first place the symptoms which it develops show at once that this drug has a very strong sympathy or influence upon the cerebral cortex. It is a delirifacient, but it is not a sleep-producer in the proper sense of the term. Albertoni made a series of experiments to determine whether it has relation with the motor zone of the cortex. He exposed the cortex in dogs poisoned with atropine, and found that the ordinary responses to galvanization of the cortical centres came; and we learn that this drug affects the centres of intellection and conscious life, but has little or no influence upon those cerebral centres which are connected with motion.

When we come lower down in the nervous system, we find ourselves in the presence of difficult problems. Many years ago Botkin found that in a frog poisoned with this drug after a certain time there is a general paralysis or muscular relaxation,* that if he tied the artery to a leg before giving the poison so that there could be no access to the nerves, that leg retained power long after the other legs were paralyzed. This, of course, could only be explained by the theory that the action of the drug in producing paralysis is peripheral upon muscle or nerve. So Botkin opened the frog's leg and tested the condition of the nerve, and found when he put the poles of the battery upon the muscle it contracted, but when he brought the poles in contact with the nerve there was little or no contraction; and he reached the conclusion, which has since been abundantly confirmed by others, that atropine is a powerful depressant to the motor nerves. It has been proven by the experiments of Meunot and of Bezold and Bloebaum, that the drug also has slight relations with the sensory nerves. Perhaps the most conclusive of these experiments were made by exposing the nerve, and putting on it a weak solution of atropine. It was found under these circumstances that very soon irritation of the nerve above the point of contact failed to produce response in the tributary muscles. For some time after this impulses would reach up toward the centre; but by and by the impulse would fail to reach the centre showing that the drug had at last blocked the afferent pathway and that it has an influence upon the sensory or afferent fibres, although it acts upon those fibres much less powerfully than it does upon the motor fibres. This was supposed to be the end of the problem, until one day Professor Frazer, of Edinburgh, found that some atropinized frogs he had put aside the day before in his laboratory as dead were in a condition of excessive life, every one in tetanus. That led to research, in which it was proven that there is a certain dose of atropine which may be given to the frog which produces complete apparent death, but in which, when the animal is left for a little time, he comes up out of this condition and passes into a state of violent tetanus. Frazer, thinking over the explanation of this, came to this conclusion, that the drug is a violent tetanic poison, acting as does strychnine upon the motor cord, but that so long as there is paralysis of the motor nerve-trunks this condition of stimulation of the nerve centres was masked by the condition of the nerve. No impulse could get out from the surging spinal sea because the channel-ways were blocked, and so the sea surged on until the ways began to be open, and then the raging waters got out and made the violent convulsions. This was a very reasonable theory: Professor Frazer supported it by various experiments bearing on it; so that it was believed to be the correct explanation until Ringer and Murrell challenged it. They found in the first place that there were certain frogs in which the paralysis never became complete, frogs in which the channel-ways remained open all the time, though there was great weakness and yet strychnine-like convulsions did not come until late. They argued if the chocked-up channelways had sufficient permeability to allow a normal impulse and movement to come through, there was sufficient permeability to allow tetanic impulses to come through. So that the fact that there was no tetanus proved that at that time there was no spinal excitement. They further found that if they tied an artery so as to shut off from the poison access to the nerve of a leg and poisoned the frog, that that leg went through exactly the same stages as did this whose nerves had not been protected from the drug. They proved in this way that masking of spinal irritation by paralyses of the nerves cannot be the explanation, of the phenomenon but that both the paralysis and the convulsion must be centric in their origin. Finally, they proved by watching certain frogs that sometimes there is a stage in which the dead frog begins to creep, but is not tetanized, only to become tetanized a little later; therefore, Ringer and Murrell said both paralysis and convulsion must be spinal and must come from one action on the spinal cord, and now I am going to ask you, in order that you may understand this matter, to leave the whole subject of belladonna for a few moments, working our way back to it.

Many years ago a very curious phenomenon was noticed in regard to the action of quinine. It was found that under the influence of quinine there is a condition in which there is complete suspension of reflex activity in the frog, so that when the impulse is sent up an afferent nerve it produces no reactions.

Nothing extraordinary in that; but the extraordinary discovery which was then made was, that if the spinal cord be divided reflex action comes back at once. Now, I know no other possible way of explaining this phenomenon except by the supposition — which to me is more than a supposition, is an established theory — that there is in the brain an inhibitory centre which dominates the motor cord, and that when you give quinine you so stimulate this inhibitory centre that it absolutely arrests action in the spinal cord, and that when you cut the spinal cord you remove the influence of this inhibition and allow the normal reflexes to return. Several other theories have been invented to explain this phenomenon: none of them are proved; all of them are complicated; and I think all are accompanied by fatal defects. I believe, therefore, that there is a centre high up in the dominant region above the spinal cord, and that quinine stops reflex activity by stimulating that centre. Now, let us return to belladonna. The theory of Ringer and Murrell is simply that belladonna paralyzes both sides or both functions of the spinal cord. Suppose, for the purpose of illustration [drawing on the board], we take this yellow line to represent the inhibitory function, the white line the motor function. He says both these lines are paralyzed. You have complete relaxation; but the action of the drug is more permanent on the yellow line than on the white, on the function of depression or inhibition than on the function of motion, and so there comes a time in the restoration of the frog when the function of motion has been restored to the spinal cord, but the function of inhibition has been, as it were, dissected out or removed. Ordinarily, when the impulse comes up to the spinal cord from the periphery, strikes a spinal cell — which we may metaphorically speak of as a bell — ordinarily, then, the impulse has a tendency to run from spinal cell to spinal cell, all through the chime of bells in the spinal cord; but it meets the restraining influence of inhibition and is so confined that only the bell rings that is needed. Atropine takes off the restraining hand of inhibition, and the impulse plays at will up and down the spinal cord ringing the whole chime; and so wild tetanic movements are developed because there is no hand to check them. I believe, therefore, that the theory of Ringer and Murrell is correct.

Again let us travel a little more afield, if you will, to certain experiments of my own during the last few months. You know the problem of chorea in the child; and the problem of the choreic movement has been one concerning which there has been a great deal of discussion and very little light. Some years since I divided the spinal cord high up in a choreic dog below the point of section and found that the movements still went on, and thus demonstrated that the choreic movement may, at least, arise in the spinal cord. I do not mean to say that every choreic movement arises in the spinal cord, but that the choreic movement may arise in the spinal cord. Without occupying more of your time, I am well assured that whilst there may be cortical choreic movements the ordinary choreic movements of childhood are largely spinal. I believe the whole motor tract is affected in the child, but that the motor cells or the spinal cord are especially connected with the choreic movement. As I was thinking over this matter, it occurred to me that when the child attempts to seize the tumbler of water and the hand goes here and there, the reason is that the motor impulse is not arrested at the proper time. We have had a great deal of discussion in our physiological books and in our works on nervous diseases about the motor impulse going to the muscle. Probably, few of us have thought that the arrest of the motor impulse at the right time is as important a part of the physiological process as the original formation of the movement. Why does the muscle in one case go to a certain point and suddenly stop? Because the inhibitory force comes down and shuts off the impulse, so that according to my belief, the inhibitory force is as active — counts for as much — as the originating impulse. The reason the child with St. Vitus dance cannot stop the movement is because its inhibition is weak. It cannot get the arrest quick enough; and the foundation of the choreic movement is, according to this thinking of mine, weakened inhibition. Then I set my wits to work to see how I should test the matter, and I thought of this action of quinine and belladonna. I got a choreic dog, and found that a little quinine thrown into a vein would stop the choreic movement. It stimulated the weakened function of inhibition, and put a hand on the choreic movement. I took another dog and injected atropine into its vein and got this result: inside of a minute the choreic movements were quadrupled by the action of belladonna, and I therefore was emboldened to put it forth as the theory that paralysis or weakness of inhibition is the basis of the choreic movement. Now, that naturally led me, of course, to the study of the action of quinine upon chorea. I have not had enough cases to speak positively; but, certainly, my results indicate that we ought to make further trials of quinine in this respect. My studies have been in all points first upon dogs, second upon human beings. The surgeons at the Veterinary Hospital of the University of Pennsylvania, have told me that they had never cured a case of chorea in the dog in the hospital. We have had seven cases, and five of them cured by quinine. In human chorea, I have seen cure in two very bad cases, one of four years' standing. Each of these cases was so bad that the child could not feed itself. The action of quinine was immediate in checking the movements; and one of the cases was finally, without any other medicine except quinine, cod-liver oil and tonics, absolutely cured. The case of two years' standing went out after six or eight weeks with simply little evidence of choreic movement in one hand. Now, I have no doubt that in those cases quinine did have some action. We have had nine cases in dispensary practice, and six of them cured by quinine in from one to two weeks. The action of quinine seemed to be somewhat temporary unless cod-liver oil and tonics be added. In other words, other remedies such as iron and cod-liver oil often have to be used to assist in permanently removing the choreic tendency. Another thing that astonished me was the amount of quinine these children can take without effect. To the child eight years old, who had had chorea two years, we gave seventeen to twenty-four grains a day for five weeks, and we never had one symptom of quinine action. There was no ringing in the ears, no deafness, no apparent influence at all from the quinine, except the child getting better. I think, therefore, that matters have gone far enough to indicate that we have in quinine a remedy that ought to be tried in chorea, probably acting upon the spinal cord in the manner in which I have spoken.

And now, gentlemen, let us return to the immediate

subject of the present lecture, belladonna; and let me give a little summary of the action of atropine. We know, in the first place, that it is a peculiar stimulant of the intellectual cerebral cortex, finally paralyzing the cortex; that it is a respiratory stimulant; that it has certain actions upon the spinal cord; that it paralyzes inhibition in the spinal cord and inhibition of the heart and inhibition in the splanchnic nerves, that is, in the intestines; that it acts as a powerful centric vaso-motor stimulant; that in some way it raises the bodily temperature; and that it produces an efflorescence of the skin. The similarity of the action of this drug to scarlet fever led, on the homeopathic principle, to its use in scarlet fever, especially as a prophylactic. It is hardly necessary to say there is little or no true or close resemblance between the action of the scarlet-fever poison and that of atropine. Many years ago the Professor of the Theory and Practice of Medicine in Jefferson College taught that belladonna is a powerful prophylactic in scarlet fever. Prof. George B. Wood, in the University, taught the opposite. There was a certain boarding-house in which both sets of students boarded. Scarlet fever broke out. Every Jefferson student took belladonna, and every University student let it alone. Many of the Jefferson students took scarlet fever, and not one of the University students got it. Reasoning as many people reason on this circumstance, we would conclude that abstinence from belladonna is a prophylactic in scarlet fever.

Now, gentlemen, we use this drug for various purposes, and all our uses are in strict relation with its physiological action. We employ it to relax spasm, and long before the physiologist worked out the problem, the clinician learned that it best relaxed spasm when he used it locally. In asthma, we give it in cigarettes. If you have a wry neck from sterno-cleido-mastoid spasm, inject the atropine into the belly of the muscle. If you have whooping-cough, give it by atomizer. Wherever you want to relax spasm, you apply it locally, and the reason is not far to seek. It acts not upon the centres, but upon the nerve, and when you bring the belladonna in contact with the nerve at the point of irritation, you relax your spasm, and hence we learn this, that this drug is not a suitable drug in those cases in which the spasm is the outcome of a general stimulation of motor centres. Formerly, belladonna was used as a hypnotic. I was taught when a student that it ranked almost with opium. Knowledge of its physiological action is borne out by the later clinical experience that this drug has no influence as a hypnotic save only in certain cases in which it puts aside spasm or pain or some disturbing influence. Then the drug was used very largely for the relief of pain. In accordance with our knowledge of its physiological action, it is of no value in relieving pain save only by relieving the spasm which produces the pain, except in certain cases as in cancers or in painful ulcers in which you can put it on the spot and affect the peripheral sensory nerves, then you get the action referred to earlier in the lecture.

A use of the drug which is perhaps not altogether appreciated by the profession is for its influence upon the blood-vessels. I want to express my conviction of the value of belladonna in the treatment of sore throats, when given in the dose of five to ten drops of the tincture every two, three or four hours, according to the susceptibility of the case. Whether it acts by impressing the blood-vessels locally or in some specific manner upon the mucous membrane, I do not know. The great value of it for the purpose of impressing the blood-vessels is seen in shock conditions. In the condition which we commonly call shock we have a state which is allied to the syncopal state, but is not the same thing. In the first place, you can kill an animal by a single blow through shock. It has been demonstrated that this occurs through irritation of the pneumogastric nerve. If you hit a man upon the stomach and he falls dead, he falls dead with heart in diastole relaxed from excessive inhibition. If you cut the par vagum of the animal, it is impossible to produce this death by shock. After the first pneumogastric stimulation of a sudden shock, often, no doubt, without this primary state, the one centric feature of shock, you have vaso-motor paralysis. The collapse and fall of temperature are but the garments that clothe over and often conceal the real centric phenomenon of the condition, namely, vaso-motor paralysis. The temperature falls, for reasons I have already explained. When I was a student in the hospitals, we used to have cases of shock in abundance, and we would pour alcohol into them and wonder we got no more effect. It seemed like pouring alcohol into a rat-hole. Alcohol is probably of no value whatever in shock; indeed, I am perfectly sure that a large dose of alcohol in shock puts one nail in the coffin of the patient, and if you want your patients to come out of shock you will be very careful in giving them alcohol. Alcohol stimulates the heart, but it paralyzes rather than stimulates the blood-vessels. It is under these circumstances that atropine becomes a remedy of the great value. Give digitalis, if you please; it helps. Give strychnine; it helps. But the one remedy which we have, which will summon any power there may be in the vaso-motor centre into immediate action, is atropine.

And now may I say to the medical men that the treatment of shock is not the prerogative of the surgeon as some believe? I believe patients sometimes die because we are not quick enough in understanding that this condition is frequently developed as a result of disease and not of injury. Not long ago I was called in consultation in a case of the puerperal variety of confusional insanity. I met the doctor, one of our best practitioners. He said to the husband: "Your wife is a good deal better this morning." As soon as my eye lit on the face, I knew she was dying from shock. The temperature was 95°, and before we could do anything 93°. In confusional insanity, whether after childbirth or surgical operations, or in the form known as delirium tremens, in all this group of insanity there is lack of nerve power as the centre of the condition; and shock or a condition allied to shock is apt to come on suddenly, and you know its presence by this fall of the bodily temperature if you cannot recognize it by your eye. In pneumonias in children, shock is a very common condition. You see it sometimes after severe rheumatism or any severe disease. When I used to see children's diseases more than at present, I noted shock at the time of the crisis or a little later, in a large proportion of severe cases of pneumonia; and under those circumstances I always used to tell the parents to get belladonna or atropine and keep it in the house so that there need be no loss of time in an emergency. When the child's temperature suddenly falls much below the normal, the sweat pours out, and the pulse weakens almost to a thread during the

third stage of pneumonia, you know you have vaso-motor paralysis; and under these conditions belladonna is the hand that will lift the child up out of the grave.

My hour is more than up and so I must leave the subject at this point. A word before we separate. It is one of the results of the remorseless march of time that that which is to be will be, and that which will be will have been; and now our time has gone, and that which came to me so unexpectedly has passed. My lectures before you are over. I only want to say that among the memories which will seem to me most precious, as crowning a life of labor, will be the picture of your intelligent faces earnestly interested in the little that I have had to say. I thank you from the bottom of my heart for your courtesy and from this time forth shall always claim with you that I have had some little part in the greatness of the Harvard Medical School.

Original Articles.

IS GERMAN MEASLES (ROTHELN OR RUBELLA) AN INDEPENDENT DISEASE?[1]

BY CHARLES P. PUTNAM, M.D.

MEASLES and scarlet fever have been distinguished from each other only in modern times. West retained even in his edition of 1873, the following: "These two diseases present many points of resemblance; so many, indeed, that they were long supposed to be but varieties of the same malady, and the essential differences between them were not recognized until within the last eighty years.[2] It is, however, on many accounts, important to distinguish between them; for not only are they not attended by the same degree of danger, but this danger arising from dissimilar causes, the treatment they require is, in many respects, different."

Now a great many physicians believe that another eruptive disease ought to be distinguished from both measles and scarlet fever, and the distinction is important for the same reasons.

A suggestive sentence in Evanson and Maunsell, edition of 1838, gives the first intimation I have seen of any division of measles. "An eruption precisely similar in appearance to that of measles is occasionally seen, especially in young infants, and runs through a regular course without catarrhal symptoms. This has been denominated rubeola sine catarrho. It requires no particular treatment, being merely a local affection, but it is generally believed by authors that it does not, like true measles, offer an immunity from future attacks."

German measles, rötheln or rubella, if there is such a disease, is not generally severe in character, but there are reasons, not only of theoretical, but of practical importance, why its differentiation should not be neglected. When we are called to see a child with an eruption, the question at once arises: Is this disease likely to be severe, or is it likely to lead to severe disease in others, and, on the other hand, from what disease will it be likely to give future protection? If we can distinguish between a regular measles and rötheln or German measles, we can answer this question much more satisfactorily. It has often happened to me to be obliged to answer the question in private families, and I will relate an instance which occurred in a large institution for children.

The Superintendent asked what should be done in view of an eruptive disease which had broken out. One child taken sick three or four days earlier had been sent to the City Hospital by another physician, as having measles, and one or two new cases had appeared.[3]

It was a matter of especial importance to the Home at that moment, for a few days later, the anniversary meeting was to be held, and many children and adults were to visit the Home. Besides, a few days later, a large number of the children were to be sent out West to be given in adoption, and both of these plans must be entirely broken up if measles had appeared. The differential diagnosis of the disease was also important on account of the individual children who were to take the disease. Would there not be a risk in sending them, as they were successively attacked, to a hospital where they would be exposed to undoubted measles?

I thought the disease was clearly not measles, but asked one day more before deciding positively. Next morning I advised them to go on with the festival and with the plans for sending the children out West on the theory that the disease was rötheln. Between May 17th and July 26th there were thirty-two cases closely resembling each other. None were sick enough to be in bed. No case was followed by any serious sequelæ. In his zeal to keep children of the same family together, the Superintendent sent off several to the West in the midst of their eruption and I believe that some broke out with the disease and went through with it while on the journey. If I had decided that the disease was measles the work of the Home would have been seriously impeded for a long time.

Each child was sent to the isolating-room as soon as any eruption was noticed, which usually happened at dressing-time or sometimes at meal-time, so that they had from four to twelve hours during which they had not been observed.

Generally the eruption was found over the whole body and almost invariably over the whole trunk. In many instances it grew thicker after admission and this was especially marked on the lower extremities. It generally lasted three or four days. Though in some cases it faded quite rapidly at first, the fading at the end was so gradual that it was hard to say exactly when the eruption disappeared and the skin became quite normal. In two or three cases it seemed almost gone, then freshened up a little and lasted a day or two more. In one case the skin did not seem quite normal until after six, and in one, not till after ten or eleven days, but in these long cases the rash did not continue bright and gave the impression that the skin had acquired a hyperæmic habit.

In each case the post-auricular, and in general, also the cervical glands were enlarged and tender. There

[1] Read before the Boston Society for Medical Improvement, March 27, 1893.

Rötheln was the name originally used in Germany, and because it was first described in that country, it was called German measles in English. Rubella has been suggested and used as the English name, and it is perhaps the best that has been used, but in this paper I adhere to the original name to avoid any possibility of confusion.

[2] Dating evidently from his first edition.

[3] I am informed that the child that was sent to the City Hospital went on May 15 and returned May 25, 1892. The diagnosis was rötheln. Eruption was gone on the 17th. She appeared perfectly well at the end of five days, stayed in the hospital, however, five days longer; discharged well.

was always more or less eruption on the soft palate and fauces, though often very faint. A little cough was noticed in some cases, though not severe in any. Headache was not infrequent, but never severe enough to give any impression of suffering. Moderate malaise was not uncommon. The temperature curves, with certain exceptions, did not go above 101°, and often not above 100°, the morning temperature being a degree or a half a degree lower; but among the thirty-two charts there were a few where it would appear that some other influence had come in, either at the beginning of the disease or at the middle of it, and there was then an exceptional temperature of 104°, 103° or 102°, for a short time. During this time there was no case of measles with the ordinary symptoms, nor any other eruptive disease.[4]

The great majority of writers believe rötheln to be an independent disease, never giving rise to any other disease, nor being derived from any other. It is mainly because a few years ago, in another society, I unexpectedly found myself the only advocate for its independence, that I thought it would be interesting to bring the subject up again. Those who do not recognize rötheln as an independent disease and consider it a mild form of measles, maintain (1) that repeated attacks of measles may occur; (2) that some epidemics are light and some are severe; (3) that in any one epidemic there is great variety in the severity of the attacks, some being so light as hardly to be recognized; and (4) that if the diseases are not identical, they see no diagnostic points by which they can be distinguished.

There is a general impression that measles often attack an individual more than once; but I think this impression is much stronger than is justified by the facts. Many writers speak of one attack of the measles giving immunity from future attacks, and do not even mention that repeated attacks sometimes occur. Those who mention the possibility of repeated attacks almost always say that they are rare.

Baginsky says they seldom occur, although he has observed them a small number of times (*einige Male*), as have also Hennig, Kassovitz, Prunac and others. Hennoch says that the re-occurrence of measles is much over-estimated, and that it is exceptional. Thomas says "extraordinarily unusual." Strümpell and Gerrhardt say that it is of the greatest infrequency, and many others use similar expressions.

My own experience has been the same. Although I have several times seen patients who said they and their friends had had it twice or three times, I have never been so fortunate as to see any one go through two attacks. On the other hand, I am not in the least disposed to deny that repeated attacks have occurred.

Of course those who believe that measles and rötheln are the same disease, have many more cases of repeated measles than those who differentiate between the two. They claim that the so-called rötheln is but a weakened measles, just as varioloid is a weakened variola. If there were but one disease, should we not find attacks varying in all degrees between the weak and the strong types, so that in some cases it would be difficult to say which is which, and yet this is not the case; for unquestionably whether we believe that these attacks must be divided into two diseases, measles and rötheln, or that they are the same disease, now in a severe type, now in a light type, it must be admitted that we can always distinguish this particular light type from the severe, if opportunity is given for a reasonably lengthy observation.

It is certainly true of all epidemics of the contagious diseases that some cases are severe and some cases are light, but this statement, as applied, for instance, to scarlatina, means that with similar symptoms the degree of severity varies very much. Epidemics in measles also vary greatly in severity, but an attack of measles may be exceedingly light and yet not present the picture given by this mooted disease. To believe in its identity, we must say there are (1) light cases of measles which resemble the severe cases closely, except that they are light, and that these light and severe cases run into each other by imperceptible degrees; but (2) that there is also a set of light cases, which differ from the severe cases in so far as they are light, but also in a variety of other ways, and do not run into the severe cases by imperceptible degrees.

The differentists do not necessarily claim to know that rötheln is caused by a different germ (for they do not know what causes either disease), but only that they can distinguish the collection of symptoms to which they give this name, from the collection of symptoms to which they confine the name of measles; and that they can tell beforehand whether the former or latter collection of symptoms will occur, as the result of contagion in another person. The identicists claim that there is no such collection of symptoms by which they can characterize a disease separate from the measles; nor do they confess to be able to tell, if these peculiar symptoms occur, whether they will, by contagion, give rise to the same mild symptoms or to the most severe symptoms of measles.

Must we then adopt this latter view and admit that no differential diagnosis can be made, either because there is but one disease before us, or because, there being perhaps two diseases, there are no diagnostic points by which they can be distinguished? Certainly those of us who have prophesied that one case would be followed by measles of unknown severity and another by an illness sure to be mild, and who have found their prophesies always fulfilled, will not be willing to accept this view.

It has been claimed that the variations and discrepances in the histories of rötheln make it impossible to make a diagnosis, and that the variations in the course of cases of measles make it possible to include all the supposed cases of rötheln under the head of measles. But the variations of rötheln seem to me to be of a non-essential kind, while the similarities are essential. Both rötheln and measles are contagious, but I have not had reason to suspect of any one case of either, that it had come from the other disease. The incubation of rötheln is apparently variable, and the limits are greater than in the case of measles. In most cases (not in all) no prodromal stage has been observed. The first symptom is usually an eruption of small, pinkish spots, which are noticed unexpectedly when a patient happens to come under more close observation than usual, as when he is bathed, when he appears at a meal, etc. Sometimes in an unusually severe case, there is a complaint of discomfort of some slight kind for twenty-four hours or possibly more, and occasionally in looking back, a patient will say that he has had some discomforts for a day before, or has noticed pain and swelling of cervical and post-auricular glands. An attack of the measles may, of course, be

[4] The thirty-two temperature charts were shown at the meeting.

very light and the symptoms may be very mild, but the prodromic symptoms almost always bear a very large proportion to the other parts of the disease. A physician is not called to a case of measles to find a large part of the body covered thickly with eruption and yet learn that this was the first notice of its existence that the disease had given.

The difference between the two diseases as regards the spread of the eruption is very well marked. You are called to a case of rötheln and told that the patient has been examined carefully a short time before and that the eruption was only on the face. But you ask to have the clothing removed and behold it has already covered nearly the whole body. With the measles, the eruption comes on tentatively in the form of isolated papules, which enlarge and coalesce and slowly go down over the body in the course of two or three days.

The color of the eruption of rötheln is rose, that of the eruption of measles is more purplish. In rötheln the papules are smaller and do not have the maculate appearance. Red patches sometimes result, but they seem rather to arise from a sympathetic hyperæmia than from coalescing of separate papules, as in case of measles. In the duration of the eruption, there is also more variation than in measles, for while three days is the usual duration, it sometimes remains visible for a longer time, but the appearance of these cases suggests that the blood-vessels have lost their true size and remain dilated rather than that the eruption is still there.

Rötheln, apparently, also has its light and severe epidemics, for some writers report cases having more severe symptoms and more severe sequelæ than others.

Stone and Davis tell of an epidemic that occurred in an orphan asylum in St. Paul; a double epidemic, rötheln appearing first, but it was soon followed by the genuine measles. Although they found in certain stages that it was difficult, by comparing the eruptions, to distinguish between them, nevertheless, they found the difference between the two diseases, taken as a whole, extremely well marked. Some of the children had both diseases, and the one or the other came first quite indiscriminately.

Variations occur in the different stages of all the eruptive diseases. Undoubtedly, in measles, it occasionally happens that the prodromic symptoms are so slight that they are overlooked. But to say that this fact prevents the differential diagnosis between measles and rötheln without regard to the other marked differences, is as illogical as to say that there is no differential diagnostic value in the short prodromic stage of scarlatina as compared with measles, because measles is sometimes not suspected until six hours before it breaks out.

In measles the fauces are sometimes so much inflamed before the eruption appears that a physician may well be in doubt for a short time whether he has before him an anomalous case of measles with an ill-marked cough, or an anomalous case of scarlatina with an accidental cough, but under such circumstances he does not hesitate to say that the future development will quickly clear up the doubt. And likewise, at any given moment, it is sometimes difficult to say whether a case is an anomalous case of rötheln, or an anomalous case of measles, but the further development makes the differential diagnosis as plain as between scarlatina and measles.

I wish to emphasize the fact that a typical rötheln does not in the least resemble a mild case of measles. A patient's skin may be covered with a brilliant rash, yet this eruption will have come in a flash and will disappear almost as fast after a very short stay, whereas the similar appearance in measles would have come on slowly, have remained longer, and have disappeared by slow degrees.

More is said about the resemblance of rötheln to measles than about its resemblance to scarlatina, but in some cases, for a short period, its resemblance to scarlatina is more striking. Scarlatina usually appears at outset in very fine red points as if, as has been said, red pepper had been sprinkled on the skin, but sometimes these spots are not so very fine and more pink than red, and then the eruption looks quite like rötheln. This resemblance, however, does not last long as the disease develops.

As Henoch has been quoted as being sceptical with regard to the independence of the disease, I quote his words: "My own experience does not justify me in coming to a decision in this question. Although I have here and there seen a couple of children in one family with a disease corresponding to rötheln of the authors, and not infrequently observed cases that left me doubtful about the diagnosis, yet I have never hitherto had an opportunity to observe epidemics or endemics of the kind such as have been described by others. So long as this is the case, I am not able to decide in the favor of the independence of rötheln."

I will add a short account of an epidemic that occurred in a family in December, 1880, and January, 1881.

On Sunday, December 26, 1880, A. L., about seventeen years old, had a slight headache and felt a little hot. After dinner an eruption of pink spots appeared on his face and spread generally over his body. By Monday morning there appeared a red blush, especially on his back and shoulders, which faded out during the day, and on the third day was almost invisible. I took it for an anomalous case of scarlatina, not being, at that time, well acquainted with rötheln, although there was but slight elevation of temperature; and, to his disgust, kept him in his room, though he seemed perfectly well, and though the eruption had faded almost as soon as it appeared, expecting to see the attack followed by desquamation; although I was obliged to confess to the family that I had never known scarlet fever to behave in this way before. This expected event, however, did not occur.

On December 30th, E. L., his sister, about thirteen years old, was found covered with a fine papular eruption, with little or no elevation of temperature, and no constitutional disturbance except a little headache and a slight weakness of the eyes. She was kept in bed from Thursday until Sunday, when the eruption was entirely gone, and she was apparently well. As with all the patients in this group, I kept her in bed, as I was not, at that time, familiar with the peculiarities of the disease. Then, after an interval of eleven days and during the next following month, there appeared eight more cases of precisely similar character.

On January 10th, H. L., was found covered with a fine papular eruption, but had little or no fever, and made no complaint except to swelling of post-auricular and cervical glands. He was in bed for two days when the rash disappeared and he got up entirely well.

On the 12th of January, the mother of the family found herself thickly covered with a similar eruption. During the day before she had noticed that the glands of her neck were tender, and she was slightly hoarse. On the same day at noon, M. L., about eight years of age, on the next day, J. L., and four days later, R. L., eighteen months of age, were attacked; each one was ill two or three days.

M. S., a housemaid, had it on the 26th of January. She had a cold at the time and some cough, nevertheless she was entirely well in three days.

An aunt who had been a constant visitor at the time, had a similar attack, beginning January 19th.

All of these patients had had measles except the two youngest children, and of these two, the elder one had measles a little over a month later, and the youngest has not had it.

To sum up, I believe that rötheln is an independent disease with its own characteristics. Though at a given moment an anomalous case of rötheln may closely resemble an anomalous case of scarlatina or an anomalous case of measles, yet this similarity rapidly disappears. Taken as a whole, rötheln differs from any other disease in its incubation, its prodromes, its invasion, its eruption (and other symptoms of the eruptive stage), its complications, its sequelæ, and finally, in the results of its contagion.

THE TREATMENT OF SENSITIVE SPINES.[1]

BY ROBERT W. LOVETT, M.D., BOSTON.

I WISH to call to your attention and to speak of the mode of treatment of an affection of the spine, the proper name of which I am unable to give. The condition is manifold, and is surrounded by much neurological obscurity as to pathology, etiology and nomenclature.

To the surgeon it appears as a sensitive and painful condition of the spine, manifested by sensitiveness most often over the spinous processes of the vertebræ, pain in motion and manipulation; and in most of the cases that I have seen it has been associated with a certain amount of general neurasthenia. The painful condition of the spine is evidently not the result of organic disease of the spine or cord, for the patients recover in most instances under proper treatment. On the other hand, with temporizing measures, the condition persists for years, varying but little, and leading generally to a bedridden and helpless condition in the severer cases.

It seems wiser for me not to attempt to speak of this condition by any other term than a sensitiveness of the spine. If I use the name, irritable spine, or any similar one, I may commit myself to some definite neurological theory without being conscious of it; and I wish merely to speak of the condition in its practical surgical aspect.

But in looking over the literature, I have found described, under various names, a condition which in some instances was identical with this and which was classed under the names, spinal concussion, spinal neurasthenia, spinal weakness, spinal irritation, functional disease of the spine, hysterical spinal disease, and the like.

[1] Read at the Boston Society for Medical Improvement, March 27, 1893.

In the cases that I have seen, in most instances it has been possible to trace the beginning of the symptoms to some injury, but in other cases the same symptoms have been present without any traumatic origin; so that it seems to me that the name for this condition should not be one which asserts anything about its causation. The injury causing the trouble was in most cases a fall, more or less severe, jarring the spinal column. In one instance, a railroad accident was the cause, in another, a wrench of the back in playing foot-ball; but in general the spinal sensitiveness was a remote rather than an immediate result of the accident. In other cases it began slowly, perhaps after some exhausting disease, as in one case after typhoid fever.

The symptoms are local and general. Locally, one finds pain and sensitiveness sometimes spread over the whole back, but at most times limited to a certain area over the vertebral column. It may be cervical or it may be confined to the sacrum and coccyx; and a fairly common situation is over the sacro-iliac joints, but in my own experience it has been most often situated in the dorsal or lumbar region. This sensitiveness is to both deep and superficial pressure. It is often sharply localized, and the pain is generally limited also to the area affected. Standing aggravates the pain, as do also riding in a carriage or car and sitting in an uncomfortable chair, so that relief is sought in recumbency. At times, the pain persists during recumbency, but even in these cases it is made worse by sitting, standing or walking.

On examination, one finds in the lighter cases a perfectly flexible spine, but motion may be voluntarily restricted in certain directions on account of the pain caused. In the severer cases the spine may be, and generally is, held quite rigid over the affected area either by voluntary or involuntary muscular effort. This stiffness is a most perplexing matter in the diagnosis at times.

There is no angular deformity such as one finds in Pott's disease, although unnatural attitudes may be assumed on account of the sensitiveness, such as a rounding out of the whole back in the dorsal region or a slight lateral deviation. The connection of lateral curvature and this spinal sensitiveness has been but little referred to. Indeed, this whole condition, so far as I can learn by my reading, has been much neglected from a therapeutic point of view.

The most important local condition has been left to the end, as to the writer's mind it is of the greatest aid in the diagnosis and the chief indication as to proper curative treatment. This condition is muscular weakness, both general and of the spinal muscles. It is to be noted on inspection and by measuring the strength of the muscles of the back by manipulation. This theory of muscular weakness, for which I am indebted to Dr. Bradford, explains the pain on the supposition that in the absence of proper muscular support the body weight comes more upon the posterior spinal ligaments and the fasciæ and aponeuroses of the back than it should, and that this is the immediate and primary cause of the pain. Just as in flat-foot, when first the muscular support gives place to ligamentous support, intolerable pain is to be felt in the ligaments. This does not, and cannot be assumed as the cause of every case of spinal sensitiveness, for it occurs at times in patients with muscles of normal strength, as measured by an apparatus for testing the back mus-

cles. The theory simply serves to explain to the surgeon the cause of most cases and to suggest to him the proper line of treatment.

This theory of insufficient muscular support does not in any way assume that congestion of the affected areas may not be present or that the blood-supply of the spine may not be seriously deranged. It only states the fact that muscular weakness is almost invariably present, that increasing the muscular support in most cases cures the sensitiveness. The condition on this supposition would seem more akin to painful flat-foot than to anything else. It is upon this theory of insufficient muscular support, generally in connection with neurasthenia, that the treatment about to be described is based.

The general condition of these patients is of the utmost importance and significance. In most cases they show marked symptoms of neurasthenia. They are, for the most part, young and middle-aged women of nervous temperament and poor development. They have such symptoms as the globus hystericus, basal headache and a stiffness at the nape of the neck, ovarian tenderness, prickling of the hands and feet, confusion in talking, and the whole class of symptoms grouped as neurasthenic. They may or may not have uterine trouble severe enough to be of account; but their symptoms of spinal sensitiveness are almost invariably worse when they are menstruating than at other times. The general condition is always poor, and, as a rule, the patients are badly nourished. They walk feebly and stiffly, and often they are entirely bedridden.

The diagnosis is generally easy from Pott's disease, which is the condition for which it is very often mistaken. But cases may occur where the diagnosis is impossible for a time.

There is no angular deformity as in Pott's disease. There is, however, extreme sensitiveness of the spine to superficial pressure, which is almost never present in Pott's disease. Flexibility of the spine is the rule; whereas in Pott's disease rigidity is marked. The presence of neurasthenic symptoms would lead one to assume the presence of the less serious disease.

In a word, the disease has no angular deformity, neurasthenia is generally present, the spine is sensitive to the touch, and flexibility is not impaired much except in advanced cases; and advanced cases of Pott's disease always show unmistakable deformity.

To illustrate the difficulty of diagnosis I may mention one case. A young man from another city came under my care last summer who had been under the care of one of the leading orthopedic surgeons of the country. He had diagnosticated Pott's disease two years previously, and had applied a steel back-brace. The young man wore it for a year or so, gradually discontinued it, had a relapse, reapplied it, and on taking it off had another relapse. Seen by a surgeon of national reputation, he was told to throw away the brace and exercise. This brought on much pain; he was crippled and bedridden, and when he came to me could scarcely walk. At this time I believe that a diagnosis was impossible. There was a suggestion of neurasthenia, and I put him to bed and overfed him. He responded at once. I gradually increased the exercise until he took an hour a day. Massage restored the flexibility to the spine and the diagnosis became clear. There was not, and probably never had been, Pott's disease. After nine months he is quite well, rides horseback and dances, and never feels any pain in his back.

The treatment which I wish to describe is not, I fancy, in any way new; but I do not know of any place where one can find it formulated for these cases, and it has in my hands yielded the most satisfactory results.

The severer cases and those in which the general condition is markedly poor should, I believe, be put to bed for some time and treated by the Weir Mitchell plan of rest and feeding. This, it seems to me, is indicated, both as a means of improving the general condition and also to quiet and rest the irritated spinal ligaments by removing the strain from them. The patients are kept entirely recumbent, and are made to use the bed-pan in the more severe cases. They are fed every hour or every two hours, taking in the twenty-four hours eight to fourteen eggs beside milk, beef-tea and meat. They are massaged gently every second day; and after a few days of this treatment, the use of faradic electricity is gradually begun on the day when massage is not given. The back is excessively sensitive, and the current is mildly applied, avoiding at first the sensitive spots. Massage and electricity rapidly diminish the sensitiveness of the spine.

After a continuance of this treatment for days or weeks, according to the general condition of the patient, she is allowed to sit up in an easy chair for five minutes, with the back supported; and then the time is rapidly increased.

At this time one begins upon exercises calculated to develop the erector spinæ muscles. These exercises have in my experience invariably aggravated the pain which is generally much diminished by the recumbency. The exercises prescribed are arch flexions of the spine when sitting; then resistance is offered to backward flexion of the trunk with the arms behind the head; and finally, when the patient is much stronger, she lies on the face and the feet are held while with the arms on the hips she flexes the trunk. It is merely, I believe, a question of prescribing easy motions which cultivate the erector spinæ muscles, and addressing them particularly to the region most affected, whether cervical, dorsal, or lumbar. One of the most successful cases that I have treated in this way was a young woman where the pain and sensitiveness were limited to the sacrum and coccyx; and it required the most intimate knowledge of the Swedish movements on the part of the masseuse to apply them so as to reach the proper muscles.

As the exercises are prescribed the patient is encouraged to walk a little; and if spinal motion is very painful, a supporting brace is allowed, which consists of a steel waist-band and two tempered, steel uprights fastened to shoulder-straps. This is used merely to support the spine until the muscles are able to do so; and is to be regarded as a temporary measure, to be abandoned at the earliest possible moment. The patient is gradually encouraged to do more each day without regard to her sensations, except during menstruation when she is kept in bed.

Personally, I always have cases where there is any question of uterine trouble examined by a gynæcologist, to be sure that no uterine displacement exists, which might cause the backache. The patient is encourged to progress as fast as may be, and to leave invalid ways behind her. The treatment is, in a word, first rest, and then muscular development in connection

with the most effective measures addressed to the general condition.

But a great many patients do not need such stringent measures as these, nor, on the other hand, can every one give up entirely for weeks or months; and a treatment which can be pursued at home and which is perfectly suitable for lighter cases must be found. These patients should be encouraged to lie down at least part of the day; even working people can save two or three hours by going to bed early. If possible, they should lie down both morning and afternoon, and should get up late. In short, the same aim of resting the back should be kept in mind as in the severer cases, and this should be accomplished in every way.

In such cases as these I apply the elastic brace almost as a routine treatment; and in one or two of the severer cases I have used a rigid steel back-brace to prevent spinal motion when the sensitiveness was severe, taking it off only for the exercises.

The general condition is most carefully looked after, the bowels are regulated, the appetite is stimulated, and eggs (from six to ten daily) are prescribed, often with a little alcohol. Walking and riding are almost invariably painful; and it is always a question how much of these should be done. It seems best at first, during the period of rest, to limit them as much as possible and to increase them very gradually, laying the chief stress upon exercise directed to the muscles affected.

Many patients cannot afford, or for some reason cannot have, massage and electricity; and yet they do well, only they progress more slowly. If attainable they are, I believe, of the utmost importance. Hot douches to the spine have often been of use in such cases. The exercises are the same as those used in the severer cases; and for the best results the cases should, I believe, be in the hands of some person skilled in massage and Swedish gymnastics. The tendency is certainly to err on the side of encouraging these patients to do too much, to walk too far and to overexercise, and one has to remember continually how great is their disability and how carefully they must be handled.

The brace is gradually discontinued, the amount of exercise increased, and the period of recumbency diminished. It is the same plan of treatment as before — first rest, and then graduated and progressive exercise; and these are no more important than is the general routine of treatment addressed to the general neurasthenia; either alone accomplishes little.

It is hardly necessary to call attention to the fact that a positive diagnosis must be made before this treatment can be successfully carried out. It is just opposite to what one would desire to do in Pott's disease; exercise always increases the pain, and a certainty on the part of the surgeon is necessary to secure the proper morale on the part of the patient.

The treatment, then, may be dismissed as consisting of general measures along with rest to the irritated ligaments, followed by active muscular exercise addressed to the supporting muscles of the spine. Electricity and massage by themselves are to be regarded only as subordinate measures to be used when practicable, and by themselves as affording very incomplete treatment. The need of counter-irritation to the back, and burning with the cautery, is not felt with the above-mentioned measures.

Clinical Department.

A CASE OF EXTRA-UTERINE PREGNANCY.

BY D. E. BAKER, M.D., NEWTONVILLE, MASS.

THE patient, twenty-four years of age, was first seen at my office in January of this year, when she complained of pain in the stomach, flatulence, rumbling of flatus in the bowels, weight and soreness in the lower abdomen. She was nervous and anæmic. She had been married five years, and four years ago had had a miscarriage at six months. She had been in ill-health much of the time for years, suffering from backache, vague pelvic pains and constipation. Tonic treatment, including iron, improved her flesh and color. Menstruation was regular until January 28th, when it failed to appear at the proper time. When nearly a week overdue, she began to complain of pain along the rectum when standing, with the feeling that the bowels ought to act; but defecation failed to give the expected relief. There was some tenderness in the left iliac region. The breasts were sore to the touch.

Examination by the vagina showed the uterus enlarged, pushed to the right and somewhat forward and lower than normal. At its left a mass, oval in shape, slightly movable and tender to the touch, could be distinctly outlined. The diagnosis of probable extra-uterine pregnancy was given the patient; and she was charged to remain in bed, as the pain and pressure were so marked when on her feet.

On examination thirteen days later, the mass had enlarged considerably and was felt lower and more behind the uterus. Sensitiveness on vaginal and rectal touch was greatly increased. Meanwhile there had been an irregular flow of dark blood from the uterus. The tumor was thought to be an unruptured tubal gestation, and the patient warned of the danger of hæmorrhage and inflammation, and advised to have the mass removed.

The next day Dr. Wood, of Waltham, saw the case in consultation and concurred in the diagnosis and the necessity for immediate operation. By courtesy of the Waltham Hospital, the patient was at once removed there for operation.

March 17th, the patient was etherized by Dr. Winslow, Drs. Wood and Cutler assisting in the operation. The abdomen was opened by an incision three inches long. No blood was visible upon entering the peritoneum; but in disturbing adhesions at the left of Douglas's fossa, a few drops of dark, extravasated blood were sponged out. A mass the size of a lemon was isolated from the left ovary and rectum, to which it adhered, and delivered through the abdominal wound, the Fallopian tube ligated, and the tumor cut away. The right ovary presented a cyst the size of a walnut, which was dissected away from its bed, and the resulting raw surface closed by sutures of fine silk. The hæmorrhage was insignificant and the shock but slight.

The patient rallied well from the ether, but for three days had a severe bronchitis, with profuse expectoration, at first mucous, later muco-purulent in character, accompanied by cough and pain in the right side. Digitalis was freely given with the nutrient enemata until the moist râles throughout the chest had cleared up and the pulse came down to 50. On the 18th an enema of salts, glycerine and water was given to re-

lieve the distention and slight colicky pain in lower abdomen. Much flatus escaped and large fæcal discharges resulted; and thereafter the bowels were moved by licorice powder.

Convalescence was rapid after the first four days. There was no fever nor untoward symptom aside from the chest disturbance following the anæsthesia. The stitches were removed on the ninth day; the patient sat up in fourteen days, and left the hospital at the end of three weeks. She is now in better health than before for several years.

Dr. F. B. Mallory, of the Harvard Medical School, reported upon the specimen as follows:

"The tumor received formed an oval mass five centimetres long and three centimetres in diameter. From the slightly smaller end hung the fimbriated end of the Fallopian tube. The oval tumor consisted of a thin-walled sac, containing a solid mass of dark clotted blood covered with a very thin membrane. This mass was adherent to the inner wall of the sac at its larger end toward the proximal extremity of the tube over an area two centimetres in diameter. The lining membrane of the sac was smooth, glistening, unstained by blood and apparently extended up over the solid mass at its point of attachment. A probe passed into either end of the Fallopian tube passed directly into the sac. The specimen when received had been cut into, and the sac retracted. In its retracted state it was from one to one and a half millimetres in thickness. Externally the tube and sac were covered with numerous fibrous adhesions. A fragment from the base of the solid mass, at its point of attachment showed on microscopic examination, typical chorion villi in a condition of marked fatty degeneration. No fœtus was found. The case is one of tubal pregnancy, with hæmorrhage into membrane."

This is the second case seen by the writer within six months. The first, diagnosticated in consultation with Dr. Carroll and advised to enter the Waltham Hospital for operation, is No. VI of the series reported by Dr. Worcester in the JOURNAL for February 2, 1893.

I recall a case I treated early in 1885 as an hæmatocele, which I now think was a tubal pregnancy. The case was a long and tedious one, complicated by recurring hæmorrhage and suppuration. I should now prefer to treat such a case by abdominal section. In none of the cases where I have opened the abdomen were the required manipulations easier to perform than in the case here reported.

An early operation, when the symptoms become threatening, clears up many anxious doubts and gives the physician control of the issues at stake as it can be obtained in no other way.

TREATMENT OF LOSS OF SEXUAL POWER BY LIGATION OF VEINS.

BY ALFRED KING, M.D., PORTLAND, ME.,
Surgeon to Maine General Hospital.

THE loss of sexual power, or rather deficient erections of the penis, render so many men miserable mentally and physically, that any new method of treatment promising a radical cure merits investigation and trial.

Three immediate causes of deficient erections may be specified: destruction of the erector muscles, loss of nerve power, and a change in the circulation. The first of these is so rare and so easily determined that it needs only a passing notice. The second cause, loss of nerve power, seems to me to have received more prominence than it deserves, as it is the basis on which almost all treatment is founded. While its force in many cases is undisputed, yet the frequent failure of treatment based upon it leads me to direct attention to the importance of the third cause, that is, a change in the circulation. This change takes place in the veins, especially those which do not pass beneath the pubic arch, or are not acted upon by the erector muscles. Repeated engorgement of the penis renders their calibre larger and, consequently, there is a more rapid escape of blood through them. When, therefore, an erection takes place, it cannot be maintained on account of the escape of blood through these channels. Thus we have the history of a gradual shortening of the duration of erections, and, finally, scarcely none if any, as these veins grow larger.

The remedy for such a condition, especially when far advanced, is not in the use of drugs, but may be brought about speedily and safely by the ligation of some of the larger of these veins.

The following case is given to illustrate this cause and its successful treatment:

Mr. M., aged thirty-five, a laborer of powerful physique, came to me about a year ago with the following history: For several years he had been losing the power of maintaining an erection, during the past year its duration having been so short that sexual intercourse had been rendered impossible. There was a loss of sexual desire and great mental depression. Excessive use or abuse was the cause of this condition.

I gave all possible encouragement to the patient; advised total abstinence from sexual intercourse, cold baths (especially to the spine and external genitals); prescribed bromides, cannabis indica, cantharides, damiana, phosphorus and salts containing it; pushed strychnine as far as it could be borne; gave various tonics; used electricity; and, in short, tried everything which offered any hope of success, but all to no effect so far as producing any stronger erections was concerned.

Careful study of the case convinced me that the immediate cause of the trouble was a physical one, due to a leakage, as it were, or to a too rapid escape of blood from the penis when erected. I, therefore, determined to ligate a couple of the larger subcutaneous veins at the base of the penis and watch the effect.

This was very easily done by the use of cocaine. A vein on each side of the penis was exposed, ligated in two places and severed between the ligatures. A dressing was lightly applied and held in position by a strip of adhesive plaster placed longitudinally. The result was immediate. In less than five minutes after leaving my office he had an erection. That night he was awakened by a powerful erection which made the bandage so painfully tight that he was obliged to jump out of bed onto the cold floor to subdue it. Primary union was prevented by the frequent erections, but the success of the operation was certain.

Two months later he reported himself well, mentally and physically; his sexual appetite had returned, and since the operation, his power of maintaining erections had been as good as ever.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR meeting, Monday, March 27, 1893, the President, DR. C. F. FOLSOM, in the chair.

DR. C. P. PUTNAM read a paper on

IS GERMAN MEASLES (RÖTHELN OR RUBELLA) AN INDEPENDENT DISEASE?[1]

DR. E. G. CUTLER: If there remain any doubt in the mind of any person present as to the dissimilarity of these two diseases, I think he ought to be convinced by consulting these charts of temperature passed about. Of the thirty-five cases, there are but two in which the temperature has reached 101°. I should think that was sufficient to stamp the dissimilarity of the two diseases. I do not recall a single instance of measles where the temperature was not elevated. In all of these cases in which there was eruption, if it were measles it seems to me that it is impossible that it could have been otherwise than that many should have shown a very considerable degree of elevation of temperature. The temperature curve is so characteristic of the true form of measles that within two or three days you can be sure of it, and the color and shape of the eruption, the place where it begins, the way it spreads, and the way it terminates are characteristic in measles; and the greater amount of enlargement of the glands, the sequelæ and the absence of any desquamation of any kind are characteristic of the other form. I had at one time a large number of children under my charge; and as one after another was admitted to this institution the history was taken off on a card or in a book, and the number of cases which had had some form of the eruptive diseases was very large. At one time we had an epidemic in this institution of what I considered to be German measles. It ran through quite a large number, and it did not spare quite a number of children who had been reported to have already had the true measles. The proportion was so great that it was not at all likely they had suffered a second attack of the true measles. I do not remember ever to have distinguished the odor in German measles that many authors speak of as so characteristic in true measles. It is quite distinct in true measles. I remember to have had three children at one time with true measles in quite a large room, and the odor was so characteristic that it was noticed by several persons who were uninstructed. At the time I had this number of German measles in the institution there was nothing characteristic about the odor.

DR. HAROLD WILLIAMS: I am sorry to say that my view is a different one from that of the gentlemen who have spoken. Before I came here I looked up the literature of the subject. I have been struck with the different descriptions given by different authors. I never have seen a case in which I could satisfy myself that rubella was a distinct disease. I have seen severe and mild measles, but never have seen a case I could say was a different disease from the mild type of measles. Now, it is a question of great practical importance whether these diseases are different. If we have measles we adopt certain very marked precautions against the dissemination of the disease, but if we speak of rubella people think it is a very mild affair and do not half carry out preventative precautions and the disease is spread. It seems to me that, practically, we are dealing simply with mild and severe measles, and that it is unwise to make this distinction until more differentiated, or a distinct bacillus is found.

DR. E. M. BUCKINGHAM: The reason that there is any question as to the identity or non-identity of these classes of diseases is probably that the so-called German measles is so mild in character that it is not well observed. The patients are not sick enough to be followed up in private practice, and they rarely get into the hospitals. It is only when such favorable opportunities occur as Dr. Putnam has had that we can conveniently study them.

We are said to have two diseases, each with an incubation and a prodromal stage, but in rubella the incubation is larger and the prodromal stage milder. Now, first, the incubation differs in measles as it does in scarlet fever; and, second, the beginning of a mild prodromal stage is likely to be overlooked, leading to the assumption of too much time as being occupied by the incubation. This is a matter of scientific consequence though seldom of practical use in making a diagnosis.

The prodromal stage in these two diseases is the same, with the difference that one is more severe than the other. That is the view that is generally taken. I had the opportunity through the kindness of Dr. Putnam, to see some of the cases he reports, and although, as he says, the prodromal stage was very slight yet there was a certain amount of catarrhal symptoms in some of them. I have also been shown other cases in which there were a set of catarrhal symptoms likely to be overlooked because of their mildness. The eruption is much alike in these two diseases. As for the eruptive stage being so mild that the case is only accidentally discovered, I have discovered scarlet fever in that same way, where, nevertheless, no one would have doubted the diagnosis. A difference in the color of the eruption is sometimes made much of as a distinguishing mark. Last summer there was an epidemic of *something* that came to the City Hospital, and I had the opportunity to point out again and again, that in a given case you would have one shade of color on one day and another on the following day. It is a fact that the color of measles does vary from day to day. Something has been said about the crescentic form of the eruption in measles as distinguishing it from German measles. I have seen two children in the same house at the same time, one with crescentic eruption and the other without, and I have seen this more than once. I am not yet prepared to speak of the size of the papules, another supposed diagnostic mark. The gland which is so generally spoken of as being found enlarged in German measles — perhaps I am not a good authority because I cannot make the diagnosis — I have seen enlarged in many cases of severe measles, and, on the other hand, this gland as it has been pointed out to me in many cases of so-called German measles, has been so small that I could with difficulty find it.

Failure of desquamation is another point relied on to prove the existence of a second disease. There are, however, a considerable number of cases of measles that would be accepted by any one as such, in which the desquamation is so slight that unless you take special pains to find it you will miss it.

[1] See page 30 of the Journal.

Dr. Putnam spoke of the hospital where they had both diseases at once. I do not see really why if one child had a light and then a severe case and another child a severe and then a light one, why that could not have been reinfection. The statement has been made that we must have two diseases because we do have two attacks. It seems that that is assuming more than we know, and it does not account for third attacks. The third attack is not particularly uncommon. You can have second attacks of scarlet fever, and of small-pox, perhaps of syphilis. I do not see why measles should not have second attacks also.

With reference to the matter of one attack protecting against another, or one of these diseases protecting against another disease, Dr. Townsend read a paper a few years ago in which he reported the results of observations where he had unusual opportunities to observe, which seemed to show that these very mild attacks do, to some extent, protect against the more severe cases, and *vice versa*.

Furthermore, I have myself seen very severe cases and very light cases of measles in the same room at the same time, one with severe and one without appreciable catarrhal symptoms.

I think that there are two arguments in favor of distinct diseases worthy of respect. One is the argument Dr. Putnam has made, that we do have epidemics in which all the cases are very light. It seems to me that when the question of there being a separate disease came up, and some one observed an epidemic in which all his cases were very light he was warranted in asking: "Is it the same disease?" and in trying to learn to make a diagnosis. That was a scientific thing to do. Years have passed, and it does not seem to me the question has been answered. Still the fact that epidemics confined entirely to light cases do exist is certainly suggestive of there being possibly two diseases; but on the other hand, it is not an unknown thing to have epidemics of other diseases which are different from each other. We do not always know the reason, but some epidemics of typhoid are more severe than other epidemics. I think the same thing is true of the whole list of contagious diseases.

There is another argument which might be offered, and that is that the majority of physicians do believe in the non-identity of these two diseases. I think that where you find a mass of intelligent men deciding on any question in their own profession, even if their reasoning is not sufficiently clear to be expressed in words, yet that the mere fact that they have a strong impression tending in one direction, as there seems to be an impression of the non-identity of these two diseases,—I think that that is an argument we have to respect; but it does not prove to my mind that they are right. It seems to me, on the whole, that the weight of argument at present is the other way; and certainly, although I am open to conviction, I cannot see that it has been proved that there are two diseases. I suppose the question may be settled in the future by the bacteriologists.

I wish Dr. Putnam would tell us how in an individual case to make the diagnosis.

DR. H. JACKSON: I think the charts which Dr. Putnam has shown us are extremely interesting. It would certainly be rare to observe 35 cases of measles in so few of which there was any rise of temperature. In one or two cases the temperature rose to 100°. In another case the temperature was on a single day 104°, but it was in the middle of the attack, so it seems to me as if the temperature must have been due to some other cause. But more interesting to me than the temperature charts was the absence of prodromal symptoms in these cases. This winter there have been a good many cases of measles, and I have been interested in noting the prolonged and often marked prodromal symptoms which preceded a very mild case of measles, notably two cases that I have in mind. The children were quite sick for three days. On the first day high temperature, less on the second and third days, and on the fourth day the full measles eruption. In one case there was no fever after the appearance of the eruption; so that the cases I have seen this winter have been mild as far as the eruptive stage and subsequent course went, but the prodromal stage in all was quite as marked as in severe cases. Also the temperature of the prodromal stage is peculiar, the temperature being high on the first day or two, and on the second or third days much less high, the temperature often being normal on the second day.

Dr. Putnam spoke of enlargement of the glands in two of his cases in private practice. I should like to ask whether any observations were made as to this point in the cases in the institution. It is spoken of by Osler as quite marked in German measles. He is very strong in his feeling that German measles is a distinct disease. He speaks of the color of the eruption, the glands, the longer course of the existence of the eruptive stage in rubella than in measles and then of its being more common in adults.

DR. ABBOTT said that he fully agreed with Dr. Putnam that measles and rötheln are distinct diseases. He well remembered the first case he ever saw, that of a man, many years ago, who consulted him as physician to out-patients at the Massachusetts General Hospital. The patient had walked to the hospital with the eruption of German measles fully developed on him. This had led him to seek advice, the constitutional symptoms being insignificant.

Since that time he had occasionally met with cases; and in some instances the diagnosis was puzzling and not to be confidently made out at the first interview. He had lately seen two cases, the patients being sisters, who had had measles in earlier life. In this instance the disease was communicated from one to the other. Neither of them required any constitutional treatment. In both of them, on each side of the neck, was a chain of small, enlarged glands, from the size of a small pea up to that of a cherry-stone; concerning which an attempt has recently been made to regard it as a pathognomonic sign of rötheln as distinguished from measles.

As to the possibility of measles occurring three times in the same individual, discussed by Dr. Putnam, he could say from personal experience that it may happen. In a family which he had attended for years he had treated three sisters for three attacks of measles, one communicating the disease to the others in each instance. The last attack was several years since, and was extremely light, with very little eruption. The catarrhal symptoms, however, were marked, and the source of the infection was positively determined. In conclusion, Dr. Abbott asked if Dr. Putnam had noticed in all his cases the chain of enlarged cervical glands which he had spoken of.

DR. C. W. TOWNSEND: I have been very much interested in Dr. Putnam's cases, that at first sight seem to be very conclusive of the existence of rötheln. I

was surprised, however, at his statement that there were no degrees between rötheln and measles, — that there were no cases that seemed half-way between the two. I think that that is a very erroneous statement, as is shown by the examination of most epidemics. The epidemic Dr. Buckingham referred to, an account of which I published, I examined with special reference to the subject of rötheln. There were 76 cases of undoubted measles, some of them of the most severe type; and at the same time with those of severe type there were some of the mild type; and a great many of the mild type were exactly like the cases described as rötheln. The prodromal stage was absent in a good many of these cases. Out of 66 where this prodromal stage was carefully noted, in 17 it was twenty-four hours or less. In eight or ten of these I believe nothing was noticed before the eruption. The catarrhal symptoms were extremely mild in many of the cases; little or no conjunctivitis in some; fever very slight. In one case, on the second day of the eruption, the temperature was 99.4°. On the third day, though the eruption was quite thick, the temperature was 100.4°; and the child also had had measles before. Another case still more striking was one I had seen two years before, in an epidemic where nearly all the cases were of the severe type. In this case the child, who had had measles before and was exposed to measles at this time, developed an eruption without any previous symptoms at all, and the eruption lasted only two days. The spots were of light pale pink color, and were not confluent. The color, I think, depends a good deal on the intensity of the eruption; and the confluence also depends on that.

Just before I came here to-night a medical student brought his brother to my office for me to make the diagnosis of measles. I promptly took him out of my office, but I saw him long enough to see that he had conjunctivitis, that he had apparently a measles eruption on his face, and the glands of his neck were swollen. He had had measles five years before, had been exposed to measles lately in Cambridge. He is feeling a little poorly, but had no symptoms before the rash appeared this morning. Temperature 100.4°. It seems to me that was a typical case of rötheln. Yet it arose from exposure to measles. We see all degrees between that case and the severe case of measles; and even the typical cases of rötheln, so-called, are not so different from the severe measles as mild scarlet fever differs from severe scarlet fever or mild typhoid fever from severe typhoid fever.

As to the enlarged glands and sore throat which are said to be characteristic of rötheln. In that epidemic where I made special note of this point the enlargement of the glands was a very varying factor. It occurred in the mild case and also in the severe case. There seemed to be no rule about it. In other words, we have all grades between typical rötheln and typical measles.

Now, as we cannot make the diagnosis from a single case — I think Dr. Putnam would admit that; even Strümpell admits that you cannot make the diagnosis very often from one case — and the chief faith in the separate existence of rötheln is founded on the fact that previous attacks of measles give no protection — the question comes how many second attacks can we have in an epidemic. There was a small epidemic at the McLean Asylum in Somerville at the same time I was studying this epidemic in Boston, occurring in ten adults who had had measles before. Measles at that time was common in Somerville. I went out and saw some of the cases, one a medical student who found the eruption coming on without any prodromal symptoms while he was in Boston. He had enlarged glands in his neck and groin; but, instead of a mild eruption like the ordinary eruption of rötheln, it was a confluent and crescentic eruption like measles. He had a temperature of 102°. The other cases were more or less severe like measles or rötheln. Now we might say this was an epidemic of rötheln as they all had measles before, or an epidemic of measles with an unusually large proportion of second attacks; but the question is where are we going to draw the line. Suppose only five of these cases had had measles before, we should then be more inclined towards the diagnosis of measles. It seems to me this almost brings the question down to a *reductio ad absurdum*. I do not mean to say that I do not believe that rötheln exists. I simply see no proof of its existence, and I should like very much to hear Dr. Putnam give us some definite way in which we can distinguish the disease.

Dr. Putnam: About the discrepancies in the description of the disease. It should be remembered that if discrepancies exist in so-called rötheln, and rötheln is a part of measles, it shows there are many more discrepancies when we take measles together, if measles includes both. There are variations in all diseases. I compared to-day two accounts of measles by different writers, and they sounded very different from each other. I believe that the essential points show similarity.

Answering Drs. Buckingham and Townsend, who say they have seen cases of undoubted measles come on where the first thing discovered was the eruption, and where the patients could give no history of prodromic symptoms of any moment, I can only say that I have not had this experience. I have lately had a mild case of measles where the eruption was so slight that it appeared only in a few spots on the skin, but the prodromic symptoms were well-marked. I have never seen a case of measles which went over the whole body in the course of a day. Measles is generally set down in the books as taking three days to go over the body. I never saw one that swept over the body in a few hours. Dr. Buckingham has seen a scarlatina where the eruption was the first thing discovered. But it is well known that in scarlet fever the prodromal stage is markedly short, whereas in measles it is markedly long.

I want to say a word about the gradations from what are spoken of as these very mild cases called rubella, and the more severe cases of measles as Dr. Townsend spoke of them, as if cases of rötheln were always like mild cases of measles or that they were always mild cases. In rötheln, the whole body, or a large part of it, may be a brilliant red, and yet the symptoms are mild. In measles, that is never the case as far as I know. When measles is light the eruption is light.

As to desquamation, I don't think much of that. I think the desquamation of measles can be avoided by keeping the patient's skin clean. I have patients with these eruptive diseases washed twice a day, and the desquamation in all of them is reduced to a minimum. I cannot say I have seen any desquamation in rötheln, but often do not see it in measles and do not say anything about it.

Dr. Abbott has reported a case of measles occurring

three times, but it seems to me the fact that it is recorded shows it is a rare occurrence. I should be glad if any member would tell us what personal experience he has of having seen measles occur twice in the same patient. I think it would be a very small number. I think very few of us can report any considerable number of these cases.

All the cases in this institution had enlarged glands. But I do not lay any stress on that because though more marked in rötheln they also occur in measles.

I stated that these two types of disease did not run into each other, and I cannot agree with Dr. Townsend that they do so; and I do not see how we can avoid thinking possibly some of those cases were German measles that occurred in that epidemic in the North End. It so happens that of these particular cases in this institution, the first case that was taken was sent to the hospital for measles. But I was convinced that these cases were not going to put the children in bed or give them any serious bronchial catarrh or any other serious symptoms, and the event proved that I was right. The same question has come up several times in private practice where there were two or three children, and I have said to people: this second one will have regular measles, or this other one will not have an illness which need be taken much into consideration.

I do not admit that I cannot make the diagnosis, and I am not willing to admit what Dr. Townsend says, that the chief refuge of the differentists is that measles does not protect from the other. I think there is no doubt that measles does occur more than once. The cases which Dr. Jeffries gave were very striking cases as relapses.

Is it possible that you should have thirty-two cases in an institution containing some hundred children where none of them had any prodromic symptoms that could be discovered except one, that no one should have had a confluent rash, that not one should have had a cough worth mentioning, or that they should be taken to have their photographs when they had been sick, and taken on a journey to the West, and some take it on the way and get well on the journey?

DR. R. W. LOVETT read a paper on

THE TREATMENT OF FUNCTIONAL AFFECTIONS OF THE SPINE (IRRITABLE SPINE).[2]

DR. G. L. WALTON: I have been very much interested in Dr. Lovett's paper. He strikes at the root of the matter in recognizing irritable spine as a symptom of neurasthenia, rather than a disease in itself. His general line of treatment is consistent with this theory. The various local remedies it has been the custom to try, such as ether-spray, hot bags, ice-bags, the cautery and iodine generally prove only temporarily useful, and it is satisfactory to have a methodical line of treatment laid out which reaches the underlying cause. Whether the symptom can be entirely explained by Dr. Bradford's theory seems to me rather doubtful. The pain in many of these cases persists even when the recumbent position is maintained, which would militate against the supposition that stretching of ligaments should be regarded an important factor in these cases at least, though the dragging pain sometimes experienced may be due to this cause. Hyperæsthesia is a common symptom, also a feeling as if the back were broken in two, a "goneness," a crawling, a grating pain, a coldness, and various other anomalous sensations, all of which may be fairly attributed to cerebral irritability rather than to a local condition. I have seen patients with such sensitive backs that the mildest application of electricity in any form would produce fainting. This can hardly be regarded as anything else than a cerebral condition.

DR. P. C. KNAPP: I have listened with much interest to Dr. Lovett's paper. I must admit that I can hardly agree with the views which he has advanced. He has described a condition which is familiar to every neurologist. I do not, however, agree with him in the symptomatology of it. A neurasthenic spine, in my experience, is not attended with that muscular rigidity of which he speaks. You get that in a certain number of the traumatic cases; but where you get the muscular rigidity it is not a true neurasthenic spine, but more of a traumatic lumbago. Furthermore, the theory which Dr. Bradford has suggested as an explanation of this pain I do not think is tenable. In the most pronounced cases of weakness of the muscles of the back, especially in the various forms of atrophy of the spinal muscles, we do not get this pain in the back. The true tenderness of the neurasthenic spine seems to me to be precisely analogous to the tenderness we get in other regions — the tenderness which is not uncommon above or below the clavicles, in the epigastrium, beneath the breasts in women, or the very familiar ovarian tenderness which is so common in hysterical subjects, and for which in times past gynæcologists have done a great deal in the way of interference, with unfortunately very little practical benefit; it is a referred pain of central origin and not due to a local lesion, and therefore I do not believe that in the true neurasthenic cases the use of the spinal brace is advisable. In the traumatic cases, where there is muscular strain the brace may often be of service. In all cases, the important thing is the general treatment, and in addition to the general treatment there is a method of treatment which Dr. Lovett has not mentioned which certainly is of the greatest benefit — the application of the galvanic current to the spine, beginning with a very mild current. In the very severe forms of neurasthenia it is necessary to put the patient in bed and to carry out Weir Mitchell's treatment to its fullest degree, but in the milder cases and in many of the cases we see in hospital practice that often becomes impracticable. The women have to keep about doing their work, and in those cases I have found that galvanism has been of the very greatest benefit.

DR. E. G. BRACKETT: I would like to bear testimony to the success that certainly attends this form of treatment in a certain class of cases that Dr. Lovett has described. There certainly are very many cases which come under the head he has described, and which are attended by the symptoms he has described, which are benefited very markedly by the line of treatment he has carried out. I have had the opportunity of seeing quite a number in the last four or five years, and have followed out very much the same line of treatment, and I think it does give some of the most satisfactory results that I have seen. There is a class of cases which he has described, and I think he has very wisely said that he should not give it any particular name — anything more than irritable spine. They are attended with neurasthenic symptoms. Perhaps I have been inclined to look at them a little more as due to local symptoms of a general neurasthenia rather

[2] See page 40 of the Journal.

than general muscular weakness, but they differ from the cases usually called neurasthenic spine, and undoubtedly require rather a different treatment than when the neurasthenic symptoms are extreme and the local less so. Most of these cases I have seen have been practically invalids for one to three years, and in that length of time there has come on a condition of chronic invalidism in which the inhibitory power of the patient has been almost entirely lost, and they have given up practically to their disease. In the treatment, it seems to me that muscular development is only a part. It is a good deal to regulate the life of a person who has lost nearly all power to practically care for themselves, as the healthy, well-regulated person should do. These are, by this method of treatment, practically put into a healthy routine; put into a way of improving their general condition. It is done by first regulating their life for them, and later allowing them to take up the reins as before they were ill; and, finally, their condition returns to health practically.

DR. GOLDTHWAIT: I have seen comparatively few cases of this sort, but I recall three very distinctly in which exactly this condition was present; and in each one of these cases there was a slight deviation of the spine and a very marked stoop-shoulder, to be explained, I think, in large part by lack of tone of the muscles and ligaments. Each of the three cases was treated in much the same manner as outlined by Dr. Lovett: two were kept in bed a few weeks, and the other was put on to exercises immediately; the symptoms very quickly disappeared. I should disagree with Dr. Knapp as to the wearing of the brace, as I think that some form of back support is advantageous. A good many of the spines are so irritable that patients on assuming the erect position complain of so much pain that they cannot go about. Some light apparatus gives them the support they need, and they are enabled to get into the open air and get the desired exercise. No doubt the cases would get well under galvanism and rest in bed, but the convalescence would be much prolonged, and I think the course of the disease is very much shortened by the application of some form of brace that allows the patient to be about.

DR. W. E. WEBBER: There are one or two points I think might be added. In regard to causation, I have found some cases where flat-foot has caused pain in the back and a condition similar to that described by Dr. Lovett, and by removing that, the trouble in the back has been relieved. I have one case in particular, in mind, in which the plates were omitted and the pain in the back returned. On resuming the use of the plates the pain in the back disappeared again. In addition to the remedies already mentioned, I have found a good deal of advantage in many cases from dry cups. I have used the rest in bed, feeding and galvanism and massage, and I think gymnastics is to be commended. I think Dr. Lovett did not mention one of the causes — lateral curvature of the spine, which is, perhaps, not a cause of the irritable spine, but one of the results of the muscular weakness, and in remedying that by gymnastics and exercise and by proper means, the pain has been relieved as well as the spine straightened.

DR. LOVETT: With regard to muscular rigidity in non-traumatic cases, I have said repeatedly that there has been a very decided rigidity of the muscles in cases where there has been no traumatism. I recall a case I saw lately in a girl of twenty years, where the trouble came on without any cause whatever. The rigidity of the spine was extreme, not perfectly stiff, but very marked, so much so that the young woman who gave the Swedish movement, said she never had seen anybody so completely tied up in every direction, but with three months of Swedish movement she has become flexible in every way.

EXHIBITION OF PATHOLOGICAL SPECIMENS.

DR. W. T. COUNCILMAN: The first case which I shall show is a very remarkable and inexplicable case of injury of the heart and lungs from violence. These specimens which consist of the heart, a portion of the right lung and of the right kidney, were taken from a strong, heavily-built man, thirty-two years old. He was cleaning the snow from a roof, and fell to the ground, a distance of about thirty feet. A large amount of snow fell with him, and it was not ascertained whether he fell on any prominent hard object on the ground. He was brought into the hospital unconscious. He partly recovered from his unconsciousness and showed symptoms which were thought to indicate cerebral injury. He died after forty-eight hours; and at the autopsy the following condition was found:

There were some old cicatrices in the brain, the result of old injury. They were found in the temporal and in the parietal lobe on the left side. They had nothing to do with his symptoms. On opening the thorax there was evidence of extensive sub-pleural hæmorrhage, more particularly on the right side. There were a few adhesions between the right lung and the pleura along its posterior border. The entire anterior and lateral portions were free from adhesions. Along the posterior part of the lower lobe of the right lung, the pleura was elevated and a large amount of blood was found beneath it. On cutting through this, there was a distinct laceration of the lung substance with an intact pleura, the lacerated portion of the lung and the lung tissue all around it, being infiltrated with blood. The laceration of the lung was irregular and about seven centimetres long. The hæmorrhage from the lung at this place had dissected up the pleura, extending to the root of the lung. Beneath the parietal pleura the hæmorrhage extended up to the apex of the cavity and into the posterior mediastinum and even to a slight extent, beneath the pleura of the left lung. Apart from the hæmorrhage into the lung, its tissues seemed absolutely intact, and on microscopic examination, no lesions were found in it. The case was apparently one of hæmorrhage and laceration of tissue in a perfectly normal lung. In the abdominal cavity there was an extensive hæmorrhage beneath the posterior peritoneum, which extended from the diaphragm into the pelvis. There was a great quantity of blood beneath the peritoneum. The source of the hæmorrhage is the right kidney. As you can see, there are a number of fractures in it. Most of these fractures are small and extend at short intervals across the kidney. The other portion of the kidney which was preserved for another purpose, had another very much larger and deeper fracture extending completely across it, and from this the most of the hæmorrhage probably came. The heart also presents interesting lesions. It is of the ordinary size, and looking at it from without, there appears to be no lesions, save a hæmorrhage, which is visible beneath the pericardium in the region of the left auricle. On examining the

interior of the heart we find in the right auricle, just above the valve, there is a distinct rupture of the endocardium. On examination you can see a torn, irregular slit of about one and one-half centimetres long, which extends for a short distance into the myocardium. This is clearly the source of the hæmorrhage which appears on the outside. A large thrombus was adherent over this fracture. A portion of this thrombus had washed away during life and there was an embolus filling up the artery of the left kidney, producing a complete infarction of this. The thorax was intact. There was no fracture of the ribs, nor of the vertebræ, nor of any of the bones of the body. There had been a little vomiting of blood shortly after he came in, and a good deal of blood was aspirated into the other lung. It is almost impossible to understand how such extensive injury as we have had here, could take place without any injury to the osseous structures of the thorax. The cases in which we have injury to the lungs are usually accompanied with fracture of the ribs. We have, however, a certain number of cases reported in which various injuries of the lung, pneumonia, and, in some cases, gangrene, have followed on severe blows of the chest, apparently without any injury to the thorax wall. A careful search here shows that there had been no previous aneurism of the pulmonary artery. It is probable that the hæmorrhage came from the ruptured lung. It could hardly be supposed that the hæmorrhage could have been the primary lesion and have produced the rupture of the lung, because at the place where the rupture has taken place, close beneath the surface of the pleura, the single arteries are not large enough to have produced by rupture, a tearing apart of the pulmonary tissue. The injury to the heart is fully as inexplicable as that of the lung. How was it possible to have this tear in the endocardium produced? The fracture of the kidney is not very uncommon, and we can very readily see how it may take place.

The next specimen is a heart which shows an interesting lesion which is due to diseases of the coronary arteries. This case comes from an individual who died at the age of eighty. He had previously enjoyed good health, but latterly had had several very severe attacks, one of which terminated in his death. The two layers of the pericardium were found tightly adherent over the apex of the left ventricle. The left ventricle, as you can see, is quite large. Its general cavity is enlarged, and the wall shows a decided increase in thickness. A great part of the enlargement of the ventricle is due to an almost perfectly circumscribed dilatation in the apex of the ventricle. This large cavity in the apex of the ventricle was almost filled with laminated clot and represents a perfectly typical aneurism. On cutting through its wall we find that the muscular substance of the heart at this point has entirely disappeared, and its place is taken by fibrous tissue. This extends over all the wall of the aneurism and into the surrounding cardiac tissue on all sides. In some other places, close beneath the endocardium, we also find some of this fibrous myocarditis. The arteries of the body generally, with the exception of a few, especially the renal artery of the left side, were comparatively intact. An interesting condition is seen in one of the coronary arteries, and to this, it is almost certain, that the aneurism is due. The artery which is affected in this case is the descending branch of the left coronary artery. Of the two coronary arteries, the left is probably the most often diseased, and the disease is generally more common in this descending branch than in any of the other branches.

The artery, as you see, is greatly thickened. There are a few patches of calcification here and there, and the lumen is almost entirely occluded. We now know that that condition of the myocardium, which we call fibrous myocarditis, is due directly to these lesions of the coronary arteries. There is an interference with the circulation of the heart over the area supplied by the diseased artery. A necrosis of the tissue is brought about. This necrotic tissue disappears and its place is taken by fibrous tissue. This gives way to the pressure of the blood within the heart and we have a cardiac aneurism.

MAINE MEDICAL ASSOCIATION.

FORTY-FIRST ANNUAL MEETING, PORTLAND, JUNE 14–16, 1893.

THE Association met, as usual for a number of years, in the Common Council Chamber, City Building, and was called to order, at 10 o'clock, A. M., Tuesday, June 14th, by the President, PROF. ALFRED MITCHELL, of Brunswick.

Prayer was offered by the REV. W. S. AYRES.

The Treasurer's report showed a cash balance of $1,198.66 — an excellent showing, considering the fact that during the past two years over $800 have been paid out in litigation over the Medical Registration Bill.

DR. G. A. PUDOR, of Portland, read a paper on

DERMAL MEDICATION.

The points emphasized were the use of fats in preference to mineral oils, as a basis for ointments when penetration of the medicament was desired, and the application of powders by a spoon instead of the usual pledget of cotton or the puff-ball.

DR. S. P. WARREN called attention to the uniformly good results following the use of icthyol ointment, one drachm to one ounce of lanoline or cosmoline, in facial erysipelas.

DR. J. L. HERSOM, of Portland, read a paper upon

DIABETES MELLITUS,

laying special stress upon nervous conditions as causes, and citing illustrative cases.

In the discussion, DR. S. C. GORDON, of Portland, took positive ground against an exclusive diet, except that he excluded potatoes absolutely, because of their tendency to produce flatulence. Saratoga chips were considered the least objectionable form of this vegetable. He did not believe in starving diabetic patients, and would forbid as food only such articles as they could not digest. Among drugs his choice was arseniate of iron.

DR. H. T. TWITCHELL, of Portland, mentioned syphilis as a cause of the disease.

The essayist, in closing the discussion, said, in response to a question, that in her experience the disease was most infrequent in children, but more rapidly fatal.

The following were elected to membership: Drs. H. J. Patterson, Portland; John Z. Shedd, North Conway; S. B. Overlock, Steuben; A. R. Smith,

Freeport; Ch. C. Larrabee, Gouldsboro; R. S. Gove, Biddeford; John S. Fogg, Biddeford; G. M. Elliot, Brunswick; J. D. Cochrane, Saco; F. I. Brown, South Portland; J. L. Fortier, Waterville.

Reports were received from the Boards of Visitors to the Portland School for Medical Instruction and the Maine Insane Hospital.

The latter stated that the present over-crowded condition of the hospital, from the failure of past legislatures to give the needed relief by necessary appropriation for a new hospital, was an imposition upon the institution, an outrage upon the patients and a disgrace to the State. The greatest capacity of the institution is, at the most, 550 patients; yet it is burdened with over 700. The report concludes: "We believe it to be the duty of every good citizen, and the especial duty of every member of this Society, to so cultivate public opinion that another legislature will not dare to longer leave this matter in such disreputable condition."

AFTERNOON SESSION.

New members were elected as follows: Drs. J. W. Conellan, Lewiston; F. L. Davis, Biddeford; J. A. Randall, Old Orchard; Wm. H. Bradford, Portland; W. D. Williamson, Gorham, N. H.; F. N. Whittier, Brunswick; George W. Weeks, Cornish; Owen P. Smith, Portland.

Delegates from other State societies were introduced and invited to participate in the discussions of the meeting. There were present Dr. Jas. F. Noyes, of Providence, R. I., and Dr. Hayden, of Connecticut.

The President, PROF. ALFRED MITCHELL, of Brunswick, then delivered the Annual Address, treating the question of

THE VALUE OF READING AS A SOURCE OF PROFESSIONAL INFORMATION.

The address was a most admirable presentation of the value, to the professional man, of the habit of daily systematic reading of standard authors in medicine and surgery, as an indispensable supplement to any course of clinical instruction or professional experience. Especially was this practice commended to those who, having passed to the middle and later years of professional life, look with almost envious and regretful eyes upon the broadened educational systems which are arranged for those who are to come after us. In no other way can we better adjust ourselves to the disadvantage which attends the former lack of special college training, laboratory instruction, the longer period of study, the graded system and the written examinations, or the inability, from whatever cause, to again undertake the curriculum of the student.

The speaker disclaimed any argument for mere bookishness, but urged that close familiarity obtained by studious association with the best professional literature was inseparable from the best equipment for professional work. It offered the best method of anticipating emergencies, and preserved us from the danger of lapsing from studious habits.

In accordance with the prescribed custom of the Association, reference was made to the state of the profession, and certain recommendations were offered. Most important was a suggestion that the Association should increase the value of its membership by some system of special requirements or professional examinations, and later this was referred to a special Committee for report at the next annual meeting; the Committee consisting of Drs. L. W. Pendleton, Chas. D. Smith, and Wm. Lawrence Dana, of Portland.

DR. I. T. DANA, of Portland, spoke upon

THE SEQUELÆ OF PNEUMONIA,

inclining to the view that all phthisis, as well as chronic pleuritis, was essentially tubercular, the dormant germ only awaiting the proper preparation of the soil by such acute disease to begin its development.

DR. A. K. P. MESERVE, of Portland, thought these cases did not originate by the pneumonia, but were the outcome of predisposition. In his experience, pneumonia, although a not uncommon disease, was not commonly followed by phthisis.

DR. C. G. ADAMS insisted upon the contagiousness of phthisis, and agreed with Dr. Dana. No communicable disease can arise except from contagion.

DR. O. St. C. O'BRIEN, of Rockport, Mass, thought if this theory were true it would do away with our accepted views upon heredity, as in the case of syphilis.

EVENING SESSION.

Dr. Chas. Mabry, of North Vassalboro, was elected to membership.

All of this session was devoted to the discussion of

APPENDICITIS,

and brought out an unusually large attendance.

A paper by DR. S. H. WEEKS presented the various indications for operation, and the technique.

DR. ALFRED KING detailed some contra-indications for operation, arising from the condition of the patient or his surroundings or the limitations of his attendant in the way of practical experience.

DR. A. K. P. MESERVE, presented a report of several cases treated without operation, resulting in complete restoration to health. The plan of treatment was that formerly regarded as the only one admissible, — perfect rest, liquid food, opiates, counter-irritation and catharsis induced by enema.

DR. S. C. GORDON in speaking upon "operation during the intervals," reiterated his well-known views upon the desirability of treating the peritonitis by salines, and when recovery has been secured to remove the cause and results of the inflammatory action. He could find no justification in always proceeding upon the assumption that to remove the cause is to cure the disease. In peritonitis from appendicitis this is conspicuously untrue, and by operation we only add new elements of danger, from more shock and sepsis, to the disease from which the patient is already suffering. He cited eight cases operated upon within the past year, during the intervals of attack, with uniformly perfect recovery.

DR. J. A. DONOVAN, of Lewiston, questioned the efficacy of Dr. Gordon's plan, and thought if adhered to in cases of suppurative appendicitis we should have many fatal cases.

DR. GORDON said he would always first try salines, even if pus did exist. If after thorough trial of this plan the elevation of temperature persisted, or it rose after once falling, he should operate; but when he could, he preferred operating during the intervals as giving the best results.

DR. N. M. MARSHALL thought he had lost patients by waiting for the action of salines.

DR. MESERVE, in reply to a query, said he had used salines not for depletive effects but simply to unload the bowels.

SECOND DAY. — MORNING SESSION.

DR. J. E. TUELL, of East Machias, read a paper reporting some surgical cases illustrating the

WORK REQUIRED OF THE COUNTRY DOCTOR.

It was valuable as showing what could be done, and what must be done by the man who cannot at any time summon the help he wishes.

DR. C. A. PEASLEE, of Wiscasset, made an interesting report of his visit as a delegate to the meeting of the Massachusetts Medical Society of 1893.

DR. CHAS. D. SMITH, of Portland, presented a paper upon

THE SIGNIFICANCE OF HÆMATURIA,

mainly clinical in character, and dealing with differential diagnosis. A point insisted upon was, that too much value should not be placed upon so-called typical cell elements in determining by microscopical examination the source of the hæmorrhage. It is often impossible to distinguish between deep urethral and vaginal cells, between the latter and superficial vesical cells. Transitional cells are often misleading, and the typical caudate cell from the renal pelvis depicted in books is rarely seen. The physician who sends urine for clinical examination, is supposed to desire information; for this reason he should give the examiner all facts bearing upon the case. Few do this, and wonder that diagnosis cannot be made from examination of urine alone.

DR. S. W. PENDLETON, of Portland, reported cases of hæmaturia from use of chloral hydrate, from malarial poisoning and another following *la grippe*. In the latter, coagula in the bladder were prevented by injection of pepsin in dilute hydrochloric acid.

DR. S. P. WARREN, of Portland, reported a case of hæmaturia which was checked by simple lavage of the bladder. A few weeks later death occurred, and the cause of hæmorrhage proved to be carcinoma of the bladder.

DR. J. A. DONOVAN, of Lewiston, read a paper on

SEPTIC POISONING: A FATAL CASE,

of interest to members, because it detailed the progress of the fatal illness of Dr. Orren A. Horr, of Lewiston, an ex-president of the Association and member of the State Board of Health. Dr. Horr died in one week after receiving a needle wound at an autopsy upon a man who died as a result of alcoholism. A curious commentary upon theory and practice was the fact that after wounding himself he gave the cut no further attention than to suck it for a moment, and then bind it up in a fragment of cloth torn from the sheet which had enveloped the body for forty-eight hours.

Drs. Geo. P. Emmons, of Lewiston, and Daniel Driscoll, of Centre Sidney, were elected to membership.

AFTERNOON SESSION.

DR. A. P. RICHMOND, of Dover, was introduced as a delegate from the New Hampshire Medical Society.

The annual election of officers resulted as follows: President, Dr. J. A. Donovan, Lewiston. First Vice-President, Dr. A. E. Besse, Waterville. Second Vice-President, Dr. O. H. Merrill, Corinna. Treasurer, Dr. Aug. S. Thayer, Portland. Corresponding Secretary, Dr. G. A. Wheeler, Castine. Board of Censors; Drs. C. A. Ring, Portland; M. B. Cobb, Biddeford; J. L. M. Willis, Eliot; F. J. Robinson, Fairfield; A. G. Young, Augusta. Committee on Publication: The Secretary, *ex-officio;* Drs. W. L. Dana, Portland; A. H. Burbank, Yarmouth; J. H. Neal, Sanford; W. T. Goodale, Saco. Business Committee: Drs. J. F. Thompson and W. B. Moulton, Portland.

DR. F. H. GERRISH, of Portland, presented a paper upon

THE TREATMENT OF PROSTATIC HYPERTROPHY,

accompanied by an improved device for permanent drainage after suprapubic cystostomy. The paper was a plea for "the establishment of a permanent fistula in the bladder above the pubes, — suprapubic cystotomy," in place of the more serious operation of prostatectomy. The advantages claimed were: "It puts the inflamed organ at rest, gives a ready opportunity for cleansing and treating the diseased mucosa, frees the patient from pain, and removes the danger of extension of the inflammation to the kidneys."

The apparatus consists of a metal plate, with rubber-ring shield and a globular chamber (fitting over the aperture), from the lower portion of which the urine, as fast as it exudes, is conducted away by a flexible tube to a convenient receptacle. The plate is secured by broad body bands.

DR. ALFRED KING thought that sepsis too frequently followed the removal of the prostate. He had found an advantage in the use of a glass syphon-tube after the operation described by Dr. Gerrish.

DR. S. C. GORDON said he had no doubt the procedure of opening the bladder to relieve prostatic trouble would be rapidly adopted. For stone, the suprapubic operation was the coming one. In an obstinate cystitis he would operate early.

DR. B. B FOSTER, of Portland, suggested the advisability under certain circumstances of making two operations instead of completing the opening at one sitting. His plan was first to make incision down to the bladder, secure union of the vesical to the abdominal wall, and enter the bladder after an interval of several days.

DR. GERRISH thought the condition of most patients demanded immediate relief, and had seen no ill effects from completing the operation at once.

DR. ADDISON S. THAYER, of Portland, called the attention of the members to the advantages of hypodermatic injections of saline solution, over transfusion of blood, in cases of hæmorrhage.

DR. ALFRED KING, necrologist, reported the deaths during the year of Dr. Henry M. Harlow, for many years Superintendent of the Maine Insane Hospital at Augusta; Dr. D. N. Skinner, of Auburn; Dr. S. A. Nash, of North Berwick; Dr. C. E. Webster, of Portland; and Dr. Orren A. Horr, of Lewiston; and presented for publication biographical notices of each.

EVENING SESSION.

This was devoted to the Annual Oration by DR. SAMUEL J. BASSFORD, of Biddeford, upon the subject of

AIDS TO SUCCESS IN MEDICINE.

These were considered under the several topics: The influence exerted by observation of the success or failure of others, the assistance of intelligent and honorable consultations, the stimulus of association with medical societies, the advantages to be gained by familiarity with carefully selected medical literature.

Following the oration, the members of the Association, the visiting delegates and their ladies, were entertained at a reception tendered by the physicians of Portland.

THIRD DAY. — CLOSING SESSION.

The Association met at 10 o'clock, A. M., and was called to order by Dr. J. L. Horr, of Westbrook, first Vice-President.

As usual, the closing hours were devoted to the sweeping up of odds and ends of unfinished business.

The Board of Censors made its final report making the assignments for the year, and fixing the date and place of the next annual meeting, as follows:

Orator: Dr. H. H. Smith, Machias. Visitors to Maine Insane Hospital: Drs. C. A. Ring, Portland; W. T. Goodale, Saco; C. D. Hill, Bethel. Visitors to Portland School for Medical Instruction: Drs. M. C. Wedgwood, Lewiston; G. M. Elliott, Brunswick. Visitor to Medical School of Maine (two years): Dr. A. K. P. Meserve, Portland. Necrologist: Dr. Alfred King, Portland.

The next annual meeting will be held in Portland on the second Wednesday, Thursday and Friday in June, 1894.

Recent Literature.

Third Biennial Report of Vital Statistics of Minnesota, for the years 1890, 1891. Minneapolis, 1893.

Very few new States have advanced so much in the matter of registration of vital statistics in the course of five years as the State of Minnesota. Much of the creditable work in this direction is due to the energetic and persevering registrar of vital statistics, Dr. C. N. Hewitt.

From this report it appears that the number of living births in the State in the census year 1890 was 32,202; and the deaths in the same year were 14,492, in a population of 1,301,826. These figures indicate a birth-rate of 24.76 per 1,000 and a death-rate of 11.13 per 1,000, the birth-rate being more than twice as great as the death-rate.

The statistics for five years were as follows:

	Births.	*Deaths.*
1887	28.615	13.010
1888	33.191	15.018
1889	31.587	14.807
1890	32.202	14.492
1891	34.107	14.714

The deaths from infectious diseases in 1891 were as follows: measles 136, scarlet fever 205, whooping-cough 224, diphtheria 720, typhoid fever 534, influenza 204, diarrhœa of children 1,126, tuberculosis of the lungs 1,268, pneumonia 897.

Traitement chirurgical des Affections inflammatoires et néoplastiques de l'Utérus et de ses Annexes — Hystérectomie abdominale et vaginale — La Castration totale par le Vagin. Par E. Doyen (de Reims). Paris, 1893.

The object of this brochure of one hundred and twenty pages is evidently to bring more prominently than heretofore before the profession the author's views of and experiences in the operations of vaginal hysterectomy and complete castration by the vagina, not only in the treatment of neoplasms of the uterus and ovaries, but also of inflammatory affections of these organs. It is his rule when both appendages are diseased to remove the uterus and tubes and ovaries by the vagina. This he has done eighty-nine times where other surgeons would have performed cœliotomies.

For neoplasms he practises both abdominal and vaginal hysterectomy, and uses clamps for the broad ligaments in both operations. Some very good drawings illustrate both methods. The book is an interesting one, though we imagine few surgeons would agree with the author in his views.

Ventilation and Heating. By John S. Billings, A.M., M.D., LL.D., etc. Pp. 500. New York: *The Engineering Record.* 1893.

Dr. Billings's new work contains much of the substance of his former excellent treatise of 1884, corrected and amplified and brought up to date. It is, however, substantially a new work, with numerous illustrations of recent practice. It will be found especially valuable as a hand-book and work of reference for boards of health, physicians, engineers, school authorities, and all persons who are or should be interested in this important subject. Technical expressions have been avoided as far as possible, and only simple formulas employed.

Of the twenty chapters contained in the work the following are some of the topics: The composition and properties of the atmosphere; carbonic acid; moisture and its relations to ventilation; quantity of air necessary for ventilation; the forces concerned in ventilation; examination and testing of ventilation (this is an especially practical chapter, and details the newer and more convenient methods in use for examining the quality of the air of inhabited apartments); methods of heating; sources of air-supply; foul-air shafts; ventilation of mines; ventilation of hospitals, public buildings, theatres, churches, schools, dwellings, tunnels, ships, prisons, etc.

The chapters on hospitals, schools and public buildings are especially useful and instructive, and like all parts of the book are fully illustrated.

On Snake-Poison: Its Action and its Antidote. By A. Mueller, M.D. Sydney: L. Bruck. 1893.

This book represents the study and experience of an Australian practitioner, extending over thirty-five years. The author likewise reviews the work of others on this subject. He holds that all of the snake-poisons exert their action by "depressing and more or less suspending the function of the motor nerve-centres throughout the body," and further that strychine is the antidote above all others, but it must be administered subcutaneously and in sufficient quantity. The writer gives an outline of fifty cases in which it was used in Australia, and notes of eight cases where it was used by R. P. Banergie, B.A., India. The Indian cases required more strychine than the Australian. Two of the former were given as much as three grains of strychine within a few days. The writer condemns the use of alcohol.

The Structures in the Mesosalpinx: Their Normal and Pathological Anatomy. By J. W. Ballantyne, M.D., and J. D. Williams, M.D. Edinburgh, 1893.

This little pamphlet contains the results of the examination of the mesosalpinx and the structures lying in it from two hundred and twenty broad ligaments. It comprises both the gross anatomy and pathology, and the histology, and is a valuable contribution to our literature of the subject.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 13, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Edtor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

EHRLICH'S URINE TEST FOR TYPHOID FEVER.

GEORGE M. BERINGER[1] has made a series of experiments to discover to what extent various substances are likely to interfere in this reaction; especially those which from internal or external administration are apt to appear in the urine, or are known to be normal or abnormal constituents. In the experiments one-per-cent. aqueous solutions were used where the solubility would permit, otherwise saturated solutions.

In applying the test, the author used the contact method, and the following modification recommended by Dr. Simon of the Johns Hopkins Hospital: "Solution 1, a saturated solution of sulphanilic acid in five-per-cent. hydrochloric acid; solution 2, a five-per-cent. solution of sodium nitrite; forty cubic centimetres of solution 1 is mixed with one cubic centimetre of solution 2, and an equal amount of urine is added and mixed. One cubic centimetre of ammonia is now carefully run down the side of the test-tube; at the junction of the two liquids there will be observed a ring of the characteristic color varying from an eosine rose to a deep garnet red."

Neutral liquids, such as alcohol, methyl alcohol, acetone, aldehyde, paraldehyde, ether, chloroform and turpentine were found to have no effect. The mineral acids and their salts, and organic acids such as lactic, oxalic, acetic, tartaric and citric acid and their salts, also gave no reaction. Salicylates and benzoates gave an orange-colored reaction, the line having a distinct green tint.

The following alkaloids and neutral principles gave also no reaction: quinine, strychnine, cinchonine, cinchonidine, morphine, codeine, cocaine, atropine, caffeine, salicin, piperine, propylamine and phenacetine.

Upon adding a few drops of a one-per-cent. antipyrine solution to the mixed reagents, there is produced at once the well-known green coloration produced by this substance with nitrites. The supernatant ammonia assumes a yellow color, separated sharply from the green solution by a brilliant red line.

Urea, uric acid, glucose and saccharose were all found to have no effect. Albumin gave an orange to a red line, depending on the amount present; two drops of a one-per-cent. solution gave a reddish orange reaction, which became a distinct red on increasing the amount of albumin. While pepsine gave but a green line, the addition of a very small quantity of peptone resulted in the production of a distinctly pale red line. The most minute quantities of phenol and creasote gave a dark red at once, and a single drop of a one-per-cent. phenol solution gave a reaction identical with that obtained from typhoid urine. Sulpho-carbolates of sodium and zinc gave a pale eosine red line, gradually darkening. Beta-naphthol gave a brilliant magenta color and resorcin a dark reddish-brown at once. Thymol and eugenol likewise produced the red line. Gallic acid and pyrogallol produce a dark red, the entire layer of ammonia quickly assuming the same color. With tannic acid the reaction is peculiar. The mixed test solutions assume an orange coloration and the ammonia becomes red, a green-colored line sharply marking the separation.

The author, in accord with others, questions the claims that have been put forth for the value of this test. While the absence of the reaction may indicate the absence of typhoid, the presence of the reaction does not warrant the diagnosis of typhoid unless supported by other evidence, as many of the substances producing the reaction, notably phenol and peptone, may be present in the urine from other causes.

[1] American Journal of Ph armacy, 1892, page 559.

THE CERTIFICATION OF REGISTERING THERMOMETERS.

THE Thermometric Bureau of the Observatory of Yale University has continued during the last year (1892–93) its comparisons of clinical thermometers and the issuance of certificates. According to the report of the Bureau, just received, only a small percentage of the instruments sold are sent for certification. Those sent for this purpose by the manufacturers are probably carefully selected, and, therefore, more reliable than the average of those sold without certification. Nevertheless, twenty-five, fifty and even seventy-five per cent. of those thus sent are sometimes rejected, and this not without these rejected instruments receiving double the care and time required by the large majority of those to which certificates are accorded.

The cost of certification adds a large percentage to the manufacturers' prices, hence, when he has succeeded in continuously producing, for a season, instruments with few and uniform corrections, the manufacturer is tempted to point to these conditions as justifying his customers in accepting his instruments without other certification than his own. The Bureau has noticed, however, in cases of this sort which have

come under its observation that apparently the workman, when he no longer has occasion to expect his work to be traversed by a disinterested authority, soon relaxes his efforts at an accuracy which is hardly yet fully appreciated by the ultimate consumer, and his instruments, when they come to it from his customers, are not quite up to the standard maintained when he was continuously, or at short intervals submitting them to such tests. Possibly, the Bureau suggests, the workman is not making due allowance for his changing standards.

The Bureau concludes its report by again calling attention to some points in the construction of registering clinical thermometers, frequently overlooked by the makers and users of these instruments, for the details of which we refer those interested in this matter — one of some little importance to medical men — to the report itself.

THE UNITED STATES MAILS A PARTNER OF EVIL QUACKS.

A VALUED correspondent writes us the following in regard to the above subject:

"I received a pamphlet the other day which, under the pretext of showing the recipient how he could be cured of the effects of self-abuse (by applying to some central office for remedies), gave an illustrated list of the effects of such practices, which included every physiological function or condition from respiration up and down.

"Believing that the circulation of such matter is far more demoralizing than a postal distribution of lottery tickets, I enclosed the pamphlet to the Postmaster-General and asked if the Post-Office Department could not put a stop to it.

"I received the within courteous reply a few days later. It would seem as though the leading medical journals and medical societies might unite in pressing the demands of the Department for legislation upon Congress, and strengthen its hand. Do you not feel inclined to take up the work in the *Medical and Surgical Journal*, asking your contemporaries to join you?"

DEAR SIR: — I have the honor to acknowledge the receipt of your letter, submitting a medical pamphlet received by you through the mails.

The Department has frequently submitted such pamphlets to United States attorneys for prosecution, but has been unable to obtain any action whatever, or conviction of the parties mailing such publications. The attention of past Congresses has also been called to the matter, and bills introduced with the view of enabling the Postmaster-General to refuse the admission of such matter to the mails; but as yet they have failed to become laws. It is hoped that some action will be taken at the next session of Congress, which will relieve the mails of these obnoxious pamphlets. Very respectfully,

FRANK H. JONES, *First Assistant Postmaster-General.*

The JOURNAL shares the sentiments expressed by this correspondent, and would be glad at any time to aid in strengthening the hands of the Post-Office Department in its efforts to rid the mails of such a pestilential nuisance. We fear, however, that with the silver and tariff questions to the front there is small chance in the next Congress for the mere moralities.

MEDICAL NOTES.

VACANCIES IN THE ARMY MEDICAL CORPS. — There are at present five vacancies in the United States Army Medical Corps, to be filled at the next examination.

A NEW BIENNIAL PRIZE. — M. Frédéric Chevallier has bequeathed to the French Academy of Medicine a sum which will afford a prize of six thousand francs, to be given every two years to the author of the best work on phthisis and its treatment.

CHOLERA. — Reports from Cairo show that the cholera, which appeared in Mecca June 9th, is increasing, there being over 200 deaths daily. In Southern France there have been 704 deaths since May, 138 deaths having occurred in Marseilles in the last four weeks.

INFLUENZA.—The New York State Board of Health reports a yielding in the epidemic of influenza, which caused during the last few months an increase of about 500 deaths a month over the average.

THE END OF MEDICAL GRADUATES. — The following from the *Medical Age* has been extensively circulated in the medical journals, and, as might be expected, has been used as a text by British journals to instruct their readers in the condition of things over here. "The writer traced after graduation 100 of his friends, especially in the first five years, and found that 75 had to resort to other employment; 23 received a salary either additional to practice or separate therefrom; 15 became proprietors of drug stores; 3 were insurance agents; 4 'loaned money'; 1 sold real estate; 1 was an agent for drugs; 1 an agent for books; 1 dealt in patent medicines; 2 were farmers; 1 a manufacturer; 2 gave massage treatment; 1 sawed wood, and subsequently suicided; 12 gave up in disgust, and 1 never tried to practice at all — 29 graduates only in 100 devoted themselves to medicine, of whom 11 associated themselves with other practitioners, and in some cases succeeded to their practice."

MEDICAL GALLANTRY. — The following shows the warmth of style of medical commencement parts prevailing farther South. No longer can the medical student be called lacking in grace and courtesy. "To the grand old city of Baltimore we must bid adieu, and to her daughters fair, for none more fair than they. (Yes, they are fair and, 'fairer than that word,' of wondrous virtues.) Sometimes 'from their eyes we do receive fair speechless message.' With us these gentle people's wishes are commands and their words law, for 'ingenious Fancy, never better pleased than when employed to accommodate the fair;' and they give us for our pains a 'world of sighs.' 'The wide world is not ignorant of their worth, for the four winds blow in, from every coast, renowned suitors,' who for many years have considered the Monumental City as the home of beautiful women. To all these we lingeringly say good-bye."

THE HARVEY TERCENTENARY. — On June 21st, the Master and Fellows of Gonville and Caius College, Cambridge, commemorated the tercentenary of William Harvey's admission to the college, by a dinner to about 130 leading physicians and scientists. A number of interesting relics and early works of Harvey were shown. The guests included the Harveian orators of the Royal College of Physicians. Speeches were made by the President of the College, Rev. B. H. Drury, M.A., Sir James Paget, Dr. Clifford Allbutt, Sir Andrew Clark, Professor Gairdner and Mr. Huxley.

A PASTEUR INSTITUTE IN THE HIMALAYAS. — A Pasteur Institute is to be established in the Punjab Himalayas for the care and study of hydrophobia. Its benefits are to be open to the whole of India, by arrangements to convey patients free of charge, when necessary, from any part of India to the Institute.

OBSTETRICAL HABITS.— Dr. Scheel, former head of the Maternity Hospital at Nancy, states that in his observation of cases of repeated childbirth, the interval between deliveries becomes shorter on the average as the number of deliveries is greater. In any one woman the same presentation occurs in 91.7 per cent. of all deliveries. The same presentation and position of the child at every delivery of a woman occurred in 51.6 per cent. of the cases. The ratio of occiput left anterior in all of a woman's deliveries, to a position of occiput right posterior was 5.07 to 1; the ratio of similar positions in all cases observed was only 2.1 to 1.

A TRADE-PRESS CONGRESS. — Among the innumerable congresses to be held in Chicago during the World's Fair, there is announced one of the trade papers. Among the questions to be discussed are the following: "What should be our relation to advertising agents?" and "What is the result of our experiences with sample copies?"

EXCISION OF AN HYDATID CYST OF THE LUNG. — Delagénière reports the following case: A woman seized with intense pain in the left side of the chest, was found to have considerable effusion in the left pleura. Puncture gave issue to a greenish puriform liquid. On incision, the lung was found adherent to the thoracic wall; the incision was carried several centimetres through lardaceous tissue bounding a cavity; this was freely opened and drained; on the following days fragments of hydatid cyst were discharged. A solution of sublimate was injected several times, but there being no improvement in the patient's condition, a large opening in the chest wall was made, twelve centimetres of the seventh and eighth ribs, and ten centimetres of the sixth, being resected; the cyst, which formed a cavity of the size of a man's fist, was then easily stripped away. The result was a complete cure.

"LONGINGS" OF PREGNANT WOMEN. — From a study of over three hundred cases, Giles, of the London Obstetrical Society, divides the healthy "longings" of pregnancy into three classes: those due to desire for something to check the sense of nausea, those which express the physiological desire for certain kinds of food, and those due in many cases to an auto-suggestion prompted by popular belief. The frequency of longing decreases as the number of conceptions increases.

A NEW SOURCE FOR CATGUT. — Dr. Dario Vigezzi, in *La Médecine Moderne*, describes a new source for animal ligatures. He proposes to use the many long tendons of dogs' tails as his source. After cutting off the tails high up and dissecting the tendons, he subjects them to a carbolic or corrosive preparation for forty-eight hours. He has used them for sutures in enterorrhaphy and on the stomach with success. Its advantages are said to be greater strength and slower absorption than are found in catgut.

NEW ENGLAND.

PUBLIC BATHS. — During the last month, 134,686 men and 25,085 women made use of the public baths of Boston, a total of 159,771, as compared with 248,847 in June, 1892. The decrease was owing to the cooler weather this year. The following are the numbers at the different houses:

Males. — At Craigie Bridge, 21,622; Malden bridge, 8,443; Dover Street bridge, 11,434; L Street, 21,334; Charles River bridge, 19,367; Maverick Street, 7,245; Mt. Washington Avenue, 8,851; Border Street, 8,467; West Boston, 19,670; Commercial Point, 1,015.

Females. — Commercial Point, 1,896; Chelsea bridge, 1,155; Malden bridge, 1,237; Dover Street, 2,522; M Street, 4,560; Border Street, 4,594; Charles River bridge, 9,121.

MASSACHUSETTS GENERAL HOSPITAL. — By the will of the late Abbot Lawrence, the Massachusetts General Hospital receives a bequest of ten thousand dollars for the establishment of free beds.

A CASE OF SMALL-POX AT NEW HAVEN. — A case of small-pox is reported from New Haven, Conn., having arrived on a schooner from Brunswick, Ga.

NEW YORK.

IMPROVED CROTON WATER. — It is gratifying to learn from the reports of the chemists of the Board of Health that the Croton Water is now in a purer condition than has been the case for many years. Nitrates have entirely disappeared from it, and it contains only trifling impurities which are the result of decayed vegetable matter. These, moreover, are constantly diminishing. This satisfactory result is said to be due in part to the heavy rainfall during the past four months, and in part to the removal of long-standing nuisances from the water-sheds of the Croton.

CABLE CAR ACCIDENTS. — Since the cable cars have been running on Broadway two persons have been killed by them. The first was a lad nine or ten years old, who was run over. The second was a man by the name of Stapleton, who was knocked down by a cable car on June 30th. He was taken in an ambulance to the New York Hospital, where he was pronounced to be suffering from a *slight contusion of the*

knee, and discharged. The next day, however, he was found dead in his room, and the Coroner's jury which investigated the case rendered a verdict, founded on the results of an autopsy made by Deputy Coroner Weston, that the deceased came to his death by being crushed between two Broadway cars, which resulted in the fracture of five ribs and of one of the cervical vertebræ.

Electric Car Accidents. — Since the introduction of the trolley system in the street railways of Brooklyn there have been a very large number of accidents (many of them fatal), and so numerous have these become of late that the Board of Aldermen have felt called upon to establish a set of strict regulations for the running of the cars.

Jumping from Brooklyn Bridge. — On July 3d a young Irishman by the name of Dennis McCarty, while in a state of intoxication, leaped from the Brooklyn bridge. He remained under water for a considerable time, and when he arose to the surface was picked up by a passing tug-boat. He was taken to Chambers Street Hospital, where it was found that he had been seriously injured. He appears to have struck the water on his right side, which was severely contused, while two of the ribs were broken. Within a day or two pleurisy developed, and it was feared that pneumonia would also result. McCarty is the fourteenth person that has jumped from the bridge.

Mortality. — Owing, no doubt, to the comparatively cool weather, the health of the city continues to be remarkably good. During the week ending July 1st the number of deaths reported was 702, which is no less than 178 below the average for the corresponding week of the past five years. During the week the number of births reported was 1,010, an excess of births over deaths of 317. There were only two cases and two deaths of typhus fever during the week, the smallest number since the outbreak of typhus commenced at the beginning of the winter. Since the 30th of November there have been reported in all 489 cases, with 208 deaths, a mortality of 42.5 per cent.

Miscellany.

MEDICAL WITNESSES AND EXPERT TESTIMONY.

Judge Hammond, of the Superior Court, at the twenty-fifth anniversary of the Cambridge Society for Medical Improvement held at the Hotel Vendome, Boston, Monday evening, June 26th, made the following pointed remarks: "The medical expert has been a poor representative of the medical profession, because of his inability to serve as a good witness. A physician's knowledge of man is very different from the knowledge of a layman; and it is very difficult to present this knowledge so that a layman can understand and appreciate it. The physician is often hampered by the stupid questions of the lawyer who frequently puts on so many conditions that it may be impossible to answer many of his questions, and no attempt should be made to do so in the form in which they are presented. The physician is often biased at the start from the fact he is retained by one or the other party. This is not a right condition of things. The physician should look the matter over and then state to the jury what, in his opinion, are important and what are not important facts in the case, without any prejudice whatever, and in as simple language as possible, so as to aid the jury as much as he can in forming their decision, much in the same manner as the judge in his address to the jury. In order that the best results should be obtained in this direction, men of special ability should be selected by the profession to act as experts, and appointed by the bar to examine and give evidence in cases requiring medical expert testimony. Action on the part of medical societies to favor and bring forth some such class of medical experts would be of great service not only to the medical but also to the legal profession."

AN EPIDEMIC OF TYPHOID FEVER.

An epidemic of typhoid fever broke out at Ironwood, Mich., a town of about 12,000 inhabitants, May 13th, and has steadily increased. There are now about 400 cases, and an average of eight deaths daily, with no signs of cessation.

The Secretary of the State Board of Health reports that on examination he found the reservoirs of the general pumping-station overflowed and the filter-pipes clogged. Water-soaked logs and the privy buildings of the engineer's family were floating in the immediate vicinity and the collected excreta had been largely washed away. Owing to the clogging of the filter-pipes a break had been made in the reservoir and the contaminated water allowed to enter the distributing reservoir, to be pumped into general circulation. This occurred between the 10th and 15th of May — the first case of typhoid fever being reported May 13th. The contamination of the water-supply was still allowed to go on till the middle of June.

A sample of the contaminating water, contained pathogenic micro-organisms which caused the death of white rats into which they had been injected, the rats then having inflamed intestines and enlarged spleens.

On cleaning the stand-pipe several tons of filth, with dead fish and crabs were found.

Although this outbreak seems to have been caused by the general water-supply, later reports show that the wells throughout the city have become contaminated and a source of danger, and that water is being brought from Milwaukee. The armories and schoolhouses have been turned into hospitals.

HYSTERICAL HÆMATEMESIS.

The not infrequent cases of hysterical hæmatemesis have been made the subject of study by M. Josserand.[1] These cases, he says, though at first somewhat puz-

[1] Lyon Medical, No. 25, 1893.

zling, have so distinct a characteristic, that the examination of the blood may be almost as pathognomonic as the expectoration in pneumonia. The more regular and early morning occurrence is of some value in the diagnosis; but the chief test is the examination of the expectoration itself. The liquid is less red than pure blood, it is more viscous, being diluted with saliva. This is especially seen when a single drop is placed on a piece of linen. The stain is not so deep and does not spread so rapidly. The blood does not, as a rule, coagulate, and is not frothy. On standing in a wine-glass it deposits three layers: An upper, red, colored by dissolved hæmoglobins; a middle, containing red globules, and a lower, which is largely made up of epithelial cells. The saliva acts as a solvent for the hæmoglobin and is present in about ten or twelve parts to one of blood. The source of the blood, chiefly from the stomach or œsophagus, may be the pharynx or base of the tongue.

The phenomenon is found most often in cases of hysteria associated with dysmenorrhœa.

LYMPHOMA OF THE CONJUNCTIVA.

M. GOLDZIEHEI[1] has reported to the Royal Society of Physicians at Buda Pesth, a case of lymphoma of the conjunctiva. It began as an intense conjunctivitis accompanied by great development of the follicles and the appearance of lymphomata in the neck. The conjunctiva of both lids was much swollen and hyperæmic. The cul-de-sac formed enormous projecting pads, œdematous and congested, and scattered with many follicular tumors and vegetations. There were also many smaller gelatinous follicles resembling highly-developed granulations. The nodules varied from the size of a lentil to that of a bean. There were no ulcerations. In the neck, on the same side, were masses of glands as large as a child's fist.

All these conditions distinguish lymphoma of the conjunctiva from trachoma, as does the slower progress of the latter. From tuberculosis it was distinguished by absence of ulceration and curability.

In this case surgical removal, with constitutional treatment, was successful.

HÆMOGLOBINURIA COMPLICATING PNEUMONIA.

DR. W. G. NASH, in the *Lancet* of June 24th, reports an interesting case of acute pneumonia accompanied by hæmoglobinuria.

A girl of sixteen, with pneumonia of the left lower lobe, on the third day passed urine of a dark yellow color, specific gravity 1,030, but with no albumen. The following day the water was distinctly bloody in color and scanty. Two days later it still being dark like porter, it was examined, as being thought indicative of more than a nephritis. Under the microscope no blood-cells were found, but numerous small red granules, a few casts and débris. The guiacum test gave a blue color. The crisis in the pneumonia occurred on the eighth day; and a few days later, the urine became normal.

[1] Le Bulletin Médical, No. 49, 1893.

There were several interesting features in the case: (1) On the fourth day only was there any expectoration; (2) the very marked anæmia and breathlessness, the latter being quite out of proportion to the amount of lung affected, and evidently due to the great blood destruction; (3) the very distressing aching all over the body, especially affecting the loins, which lasted several days and was no doubt due to the blood change; and (4) the fact that on the fifth day the temperature in the axilla was 98.2°, and in the mouth 103°, this being apparently due to the contraction of the peripheral vessels.

CRYPTOPHTHALMUS.

FUCHS[1] recently showed to the Royal Society of Physicians at Vienna, a case of cryptophthalmus. The child, who was born of healthy parents, had no eyelids, but in their place, a continuous covering of skin on which were no lashes or eyebrows. Careful examination detected no tarsal cartilages. There were, however, some muscular fibres corresponding to the orbicularis, since a strong light caused the child to wrinkle the skin over the eye. The child was also web-fingered.

This is the fourth case thus far recorded.

HÆMORRHAGE IN THE CENTRUM OVALE.

AFFECTIONS of the centrum ovale have few constant or characteristic symptoms. Many cases are quite latent; the signs of others bear reference to the cortex or adjacent basil portions of the brain. In the case of hæmorrhage, the indirect symptoms give additional difficulty to the diagnosis. Bamberger has had the observation of four cases, all similar in character, in two of which the autopsy confirmed the ante-mortem diagnosis. The other two were not examined after death. The cases were characterized by deep coma, markedly flushed faces, hæmiplegia, epileptic convulsions in the paralyzed side, and gradual cessation of life.

The Jacksonian epilepsy distinguished these hæmorrhages from all others. The differential diagnosis lay between cortical hæmorrhage and hæmorrhagic pachymeningitis. The diagnosis of hæmorrhage in the centrum ovale has a bearing on the prognosis, and especially on the care of the case as regards trephining.

PARENCHYMATOUS INJECTIONS IN THE TONSIL.

VON ZIEMSSEN[2] reports that he has found the injection of carbolic acid into the parenchyma of the tonsil, useful not only in the treatment of scarlatinal diphtheria as recommended by Traube and Heubner, but also in ordinary simple tonsillitis whether follicular or suppurative. He bases his treatment on the belief that nearly all cases of tonsillar angina are of an infectious nature, inasmuch as the presence of streptococci, staphylococci and diplococci are constantly found in the crypts of the tonsil. An abrasion of the epi-

[1] Deutsche Medizinal Zeitung, No. 50, 1893.
[2] Beilage Zum. Centralblatt für klin. Medical, 1893, 25.

thelium is all that is needed to give them pathogenic entrance.

In catarrhal tonsillitis his treatment consists in the injection of one-half a cubic centimetre of a two-per-cent. solution of carbolic acid into the substance of the tonsil. The pain and difficult deglutition are at once lessened and the temperature falls to normal or below. As a rule, one injection is sufficient. Sahli of Bern and Heubner concur in the statement of Von Zeimssen as to the value of this treatment.

THE BACTERIOLOGY OF SUPPURATIVE MENINGITIS.[1]

ZORKENDORFER reports a case in support of the theory advanced by Fraenkel and others of the etiological relation of the pneumococcus to purulent meningitis. Autopsy in this case, which was one of purulent meningitis uncomplicated by any pneumonia, showed greenish-yellow pus in the sphenoidal cavities, and a suppurative pharyngitis. The pus taken from the meninges and from the sphenoidal cells was found microscopically to contain pneumococci. Cultures and inoculation also showed their presence in the meninges, in pure cultures and elsewhere with other cocci. Section of the brain showed the diplococci only in the purulent meninges — in no instance in the brain substance or the blood-vessels.

INFANTILE DIABETES.

IN the various text-books on children's diseases very little is said about diabetes except that it is exceedingly rare in children. The difficulty of obtaining the urine of very young children for examination, may be one reason for the failure of early diagnosis in such cases as do occur, and the marasmus is referred to other causes. In spite of its rarity the disease is not so infrequent as might be supposed; and Duflocq and Dauchez's report[2] of such cases occurring in very young children is not without interest. The patient, a boy of eighteen months, had always been well, save for a tendency to constipation. For a fortnight previous to observation, he had had great thirst, drinking two and a half litres of sterilized milk daily. Micturition was frequent. He was peevish, and groaned in his sleep. The loss of weight and fretfulness was attributed to dentition. The temperature was 37.8° C. The pulse was feeble, and there was some cyanosis. During the night the child failed much, became cyanotic, moaned, and vomited several times; temperature 36.5° C. From this condition he rapidly passed to one of coma, with quick respiration, dilated and immovable pupils, and died during the day. From examination of dried napkins a considerable percentage of sugar was found.

There was heredity in the case, a great uncle having died of diabetes.

In examining this and other cases the following conclusions were reached: Among the earliest symptoms is the change in disposition — a wearied querulousness, unaccountable sobbing in the midst of play. Constipation appeared not infrequently. The increased urination is often ascribed to the ingestion of much milk, which is mistaken for a hearty appetite. The occurrence of dentition is looked upon as causing the loss of sleep and wasting of flesh. The course of the disease is rapid; and a sudden unexpected coma may first call serious attention to the case.

[2] Revue de Médecine, 1893, No. 6.

THERAPEUTIC NOTES.

A CASE OF ANTIPYRINE HABIT. — A case of antipyrine habit is reported, in which the patient, a nervous woman of twenty-three, had used the drug for headache. For two years she had taken nearly eight grammes a day. The symptoms were those of great prostration, muscular weakness and insomnia. In the gradual reduction of the dose caffeine was used to meet the functional disturbance. A cure was finally accomplished.

SALICYLIC ACID FOR TAPE-WORM. — Ozegovski recommends the following treatment for tape-worm. The patient takes no mid-day or evening meal, and at bedtime is given 30 grammes of castor-oil. The following morning at 7 o'clock a second dose of 15 grammes of castor-oil is given. An hour later one gramme of salicylic acid is given, to be repeated every hour to four doses. If the worm is not expelled by this time a third dose of castor-oil is indicated.[1]

DIGITAL COMPRESSION IN THE VOMITING OF ANÆSTHESIA. — Dr. Bernard Joos [2] describes a method for the control of the hiccough and vomiting during anæsthesia, which he has found successful for several years. It consists in digital compression of the phrenic and vagus nerve against the sternal end of the clavicle. His method is as follows: As soon as singultus or vomiting begins, the etherizer presses the last phalanx of the left thumb firmly over the sternal end of the clavicle, the body of the thumb being parallel with the clavicle and the hand resting on the chest. The pressure is made with the radial side of the thumb. The vomiting stops at once, as a rule. If needed, or more convenient, the pressure may be made on the right side. Pressure is continued for a few moments to prevent a return of the vomiting. He recommends the trial of this method in cases of sea-sickness.

Amesbury	10,920	3	0	33.33	33.33	—	—	—

Deaths reported 2,908: under five years of age 1,293; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 672, diarrhœal diseases 366, consumption 313, acute lung diseases 278, diphtheria and croup 136, typhoid fever 39, whooping-cough 33, measles 31, scarlet fever 31, cerebro-spinal meningitis 20, erysipelas 6, malarial fever 6, small-pox 2, typhus fever 2.

From whooping-cough New York 8, Philadelphia 7, Brooklyn 5, Chicago, Cincinnati and Pittsburgh 3 each, Nashville 2, Boston and Portland 1 each. From measles New York and Pittsburgh 12 each, Chicago 4, Philadelphia, Brooklyn and Cincinnati 1 each. From scarlet fever Pittsburgh 8, Brooklyn 7, New York 4, Boston 3, Philadelphia, Milwaukee and Fall River 2 each, New Bedford, Waltham and Amesbury 1 each. From cerebro-spinal meningitis New York 6, Chicago and Washington 3 each, Cleveland, Worcester and Lynn 2 each, Brooklyn and Milwaukee 1 each. From erysipelas Chicago and Boston 2 each, New York and Philadelphia 1 each. From typhus fever New York 2. From small-pox New York and Chicago 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending June 17th, the death-rate was 19.4. Deaths reported 3,842; acute diseases of the respiratory organs (London) 234, diarrhœa 250, measles 143, whooping-cough 89, diphtheria 81, scarlet fever 74, fever 20, small-pox (London 6, West Ham, Birmingham and Manchester 2 each, Nottingham, Derby, Oldham, Halifax, Bradford, Sheffield and Hull 1 each) 19.

The death-rates ranged from 10.3 in Portsmouth to 32.2 in Swansea; Birmingham 15.3, Bradford 19.1, Croydon 16.3, Hull 20.2, Leeds 15.8, Leicester 18.5, Liverpool 28.9, London 19.1, Manchester 25.0, Newcastle-on-Tyne 14.6, Nottingham 12.1, Preston 15.5, Sheffield 18.9, Sunderland 19.0.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending June 24th, the death-rate was 22.1. Deaths reported 4,377; acute diseases of the respiratory organs (London) 252, diarrhœa 496, measles 128, whooping-cough 95, diphtheria 86, scarlet fever 54, fever 41, small-pox (London 11, Bradford 4, Birmingham, Oldham and Halifax 2 each, West Ham, Birkenhead and Manchester 1 each) 24.

The death-rates ranged from 11.5 in Norwich to 32.9 in Liverpool; Birmingham 21.4, Bolton 20.5, Bradford 19.8, Croydon 18.2, Hull 17.0, Leeds 19.9, Leicester 24.6, London 22.6, Manchester 26.6, Newcastle-on-Tyne 21.4, Nottingham 15.8, Oldham 19.9, Salford 26.9, Sheffield 22.8, West Ham 14.4.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 8, 1893.

JAMES S. LEYS, commissioned an assistant surgeon in the Navy.

G. S. BEARDSLEY, medical director, detached from Navy Yard, Washington, D. C.

C. H. WHITE, medical inspector, detached from Smithsonian Institution.

JOHN C. WISE, surgeon, ordered to Navy Yard, Washington, D. C.

C. U. GRAVATT, surgeon, ordered to the Smithsonian Institution.

C. D. W. BROWNELL, assistant surgeon, detached from the U. S. S. "Newark" and granted one month's sick leave.

S. G. EVANS, assistant surgeon, ordered to the U. S. Receiving-ship "St. Louis."

C. W. RUSH, passed assistant surgeon, ordered before Retiring Board.

THE PAN-AMERICAN MEDICAL CONGRESS EXCURSION TO ROME.

It has been definitely determined that the Pan-American Medical Congress Excursion to the Eleventh International Medical Congress will sail on the S. S. *Werra* from New York, September 9th, the day following the adjournment of the Congress at Washington, and will arrive at Genoa, September 20th, four days before the opening of the Rome meeting.

Round-trip steamer tickets may be procured for $142.50 for inside rooms, and $150 and upwards for outside rooms. Tickets are good for members of the Congress and their families and may be used at option of holder to return on any steamer of the line from Genoa, or on Saturday steamers from Bremen, or Sunday steamers from Southampton, during the months of October, November and December. This exceptional rate is made for members of the Pan-American Medical Congress.

RECENT DEATHS.

BENJAMIN A. FORDYCE, M.D., of Union Springs, N. Y., died June 3d, aged seventy years. During the Rebellion he was assistant surgeon of the 160th Regiment of New York Volunteers. He was at one time President of the New York State Medical Association.

REV. E. P. THWING, M.D., died in Canton, China, of typhoid fever. He was a graduate of the Andover Theological Seminary and of the Long Island College Hospital. He was actively interested in starting a hospital for the insane in connection with his missionary work.

BOOKS AND PAMPHLETS RECEIVED.

Twenty-sixth Annual Report of the Massachusetts Infant Asylum. 1893.

Catalogue of the Albany Medical College, Sixty-second Session, 1892–93, and Announcement for Session, 1893–94.

Zur Therapie der Hautkrebse. By Dr. Oscar Lassar. Sonderabdruck aus der Berliner klinschen Wochenschrift. 1893.

Pathology of the Vermiform Appendix. By T. N. Kelynack, M.D. With illustrations and bibliography. London: H. K. Lewis. 1893.

Bibliographie der Klinischen Helminthologie; Ascaris, Oxyuris, Trichocephalus, Ankylostomum. Von Medicinalrat Dr. J. Ch. Huber. 1893.

Colles' Fracture; Illustrated by Splints used in Treatment and by Photographs of Cases. By E. H. Woolsey, M.D., Oakland, Cal. Reprint. 1892.

Nostrums for increasing the Yield of Butter. By Harvey W. Wiley, Chemist of the United States Department of Agriculture. Farmers' Bulletin, No. 12. Washington. 1893.

Traitement des Végétations Génitales Chez la Femme. Du Bleu de Méthylène comme Traitement dans Différentes Maladies Infectieuses et Particulièrement dans la Vaginite Purulente d'Origine Blenorragique. Par G. Richard D'Aulnay. Reprint. 1893.

An Ovarian Tumor Weighing 111 Pounds Removed from a Child of Fifteen, whose Weight was 68 Pounds. The Real Rewards of Medicine. Laparotomy for Apparent Intestinal Paralysis which Caused Arrest of the Intestinal Contents and was Equivalent to Intestinal Obstruction. Case of Cancer of the Hepatic Flexure of the Colon Producing Intestinal Obstruction; Temporary Relief by an Artificial Anus; Later Re-establishment of the Continuity of the Bowel by Ileo-Colostomy by means of Murphy's Button. By William W. Keen, M.D., of Philadelphia. 1893.

Lecture.

TUBERCULOUS PLEURISY.[1]

THE SHATTUCK LECTURE FOR 1893.

BY WILLIAM OSLER, M.D.,
Professor of Medicine in Johns Hopkins Hospital, Baltimore.

MR. PRESIDENT AND FELLOWS: — Many members of your ancient and honorable body (Bowditch, Wyman, Ellis, Garland, Sears and others), have dealt with many problems in connection with pleurisy; and without making invidious comparisons it may be said that their contributions, more particularly those of the late Henry I. Bowditch, are the most important which have been made on the subject in this country. While modesty made me hesitate to select any question relating to pleurisy as the topic for the Shattuck Lecture of this Society, I felt that differences of opinion on many points — not the least on those concerning the frequency, varieties and sequences of the form known as tuberculous — would justify the narration of an experience gleaned during the first four years of service in the medical wards of the Johns Hopkins Hospital.

I. INCIDENCE OF TUBERCULOUS PLEURISY IN THE POST-MORTEM ROOM AND IN THE WARDS.

(*a*) *In the Post-Mortem Room.* — A trustworthy estimate of the incidence of tuberculous pleurisy can be had only by anatomical investigation. Uncertainty is inherent to clinical records of an affection such as pleurisy, the diverse etiological factors of which cannot be always discriminated at the bedside, even with the help of bacteriology.

Accordingly, with the kind assistance of Dr. Rupert Norton, and with the consent of my colleague, Professor Welch, I have carefully analyzed the post-mortem records of the 101 successive cases from my wards in which pleurisy — fibrinous, sero-fibrinous, hæmorrhagic or purulent — was found; and the record is of interest as showing the incidence of tuberculous pleurisy in a medical service varying from 70 to 90 beds. There were 32 cases out of 101 in which the pleurisy was definitely tuberculous. I have estimated as such only those in which tubercles were present on the pleural layers, either as fresh miliary granulations, caseous masses or diffuse fibro-tuberculous membranes. Of these cases there were eight with purulent exudate, all associated with pneumothorax, and two with hæmorrhagic fluid. Seven were cases of acute miliary tuberculosis with fibrinous and sero-fibrinous exudate; four were instances of acute miliary tuberculosis with a purely fibrinous effusion; and thirteen were cases of chronic sero-fibrinous exudate with more or less thickening of the pleural layers. In four instances the sero-fibrinous exudate was encapsulated.

There were thirteen cases of pulmonary tuberculosis in which pleurisy was present without our being able to say definitely that it was of a tuberculous nature. In ten of these cases the exudate was fibrinous, and three sero-fibrinous. It will thus be seen that the incidence of tuberculous pleurisy among these 101 cases was a little less than 32 per cent. By far the most common forms of pleurisy are the sero-fibrinous and fibrinous, secondary to acute disease of the lungs, or occurring as a terminal process in chronic affections of the heart, arteries or kidneys.

[1] Delivered before the Massachusetts Medical Society, June 13, 1893.

(*b*) *In the Wards.* — Passing now from the certain and definite data of the post-mortem room, let us turn to the wards and inquire into the etiology of the cases of acute pleurisy which have been under observation. I have thought it better to review only those cases in which there has been a pleurisy with effusion coming on acutely or subacutely, and in which the effusion was sero-fibrinous, not simply fibrinous and not purulent. I have excluded the former from analysis because of the very great frequency, as the post-mortem reports show, of a simple fibrinous pleurisy in so many varied conditions, often overlooked clinically, of which, of course, tuberculosis is one, indeed one of the most common. I have not included the purulent cases, partly because there is here much less dispute, as they have a more definite and well-recognized etiology, and partly from the fact that abscess of the pleura — empyema — is regarded with us as a strictly surgical affection, and the cases are either admitted directly to the surgical wards or turned over at once. This may account for the somewhat remarkable absence of purulent pleurisies in the post-mortem records of cases from my wards, apart from the instances of pneumothorax. Still it must be noted that of 14 cases of empyema operated upon, 12 recovered, exclusive of the cases of empyema with pneumothorax. The cases in the following analysis, then, have been admitted to the wards with well-marked signs of pleurisy with effusion. Of the 58 cases 45 were males, 13 females; 10 were in the colored race, 48 in the white.

In attempting to estimate from the clinical side the tuberculous character of a pleurisy the following points are to be considered:

(1) Mode of onset. In reality this is not a criterion of any moment since it must be acknowledged that an acute tuberculosis of the pleura may come on abruptly with a stitch in the side, or even with a chill. A slow insidious onset is more common, but by no means characteristic.

It is so difficult to obtain from hospital patients accurate information as to the mode of onset, often indeed as to the duration of their illness before admission, that we cannot place very much reliance upon the facts so obtained; but the errors, I suppose, are equally common throughout the entire class. As a general rule, too, the patients do not seek relief until the symptoms have become aggravated. Thus it is interesting to note that in the 58 cases of sero-fibrinous pleurisy the duration of illness prior to admission was given as one week and under in 8 cases; between one and two weeks, 16 cases; between two and three weeks, 7 cases; one month and over, 25 cases.

Of the symptoms for which they sought relief the following were the most striking: In 2 cases no history could be obtained. Of the remaining 56 cases the symptoms for which they sought relief were, as a rule, cough, dyspnœa and pain in the side; more rarely fever or chills and fever. Thus, in 45 cases, the patient complained of cough; in 44 of dyspnœa; in 41 of pain in the side; and in 14 there was a history of chills and fever. Cough and dyspnœa are by far the most frequent causes for which the patient seeks relief in hospital. In two only of the cases did the patient give any definite account of an exposure to cold or of a wetting. As stated, the onset is no etiological criterion, and the claim at present is, that a great majority of the cases of pleurisy *a frigore* are, in reality, tuberculous. In the history obtained from the patient, how-

ever, there may be very suggestive features; for instance, cough and loss of weight for some months previous, or hæmoptysis, or a previous attack of pleurisy. Thus, one patient, Case 1 of the series, had had a cough at intervals for three years, and when admitted, the right side of the chest was full of greenish, sero-purulent fluid. After many tappings he improved very much, and, though the cough had persisted for so long, there was no sign of pulmonary disease, but subsequently bacilli were found in the expectoration. Another interesting case, No. 4, had hæmoptysis nine months before, and though he was an extremely robust, vigorous man, the insidious onset of the pleurisy led us to suspect tuberculosis. Bacilli were demonstrated in the exudate. The patient subsequently developed pulmonary tuberculosis. In two instances only the patients had pleurisy with effusion previously; in one, five months before; in the other, eight years before. Both did well, and both were discharged at at the end of three weeks.

(2) A point, on which more stress has been laid than the facts justify, is the family history; but inheritance is now generally acknowledged to be of a susceptible soil, rarely of the germ itself. Local conditions are probably of most importance in influencing the susceptibility to an infectious agent so widely diffused as that of tuberculosis. Still it is interesting to note the presence or absence of tuberculosis in the ascendants or near relatives; thus in two of the fifty-eight cases the father died of tuberculosis; in four, the mother; in one, the father and mother; in six, a brother or sister; in one, a brother and sister; in four, an aunt or uncle; and in two the wife died of tuberculosis, in one the husband. In 37 of the cases positive questions as to tuberculosis in the family were answered in the negative, and in three it could not be obtained.

(3) The character and contents of the exudate. There is nothing specific in the physical character of the effusion in tuberculous pleurisy, nothing from which on aspiration a definite opinion can be formed. The exudate may be sero-fibrinous, simply serous, hæmorrhagic, sero-purulent or purulent. Of these, hæmorrhagic and the thin sero-purulent may be called suggestive. Of the cases of acute pleurisy with effusion, at the clinic, seven were blood-tinged. Of the cases from the wards in which pleurisy was found post-mortem, in four the effusion was hæmorrhagic; of these, two were tuberculous and two were simple. The thin sero-purulent exudate, a little opalescent, often with a greenish tint, and which microscopically contains a granular, fatty matter and only a few leucocytes, is very suggestive of a tuberculous lesion. The cover-slip and culture-tests, so much practised of late, yield variable results. In the first place it is conceded that the great majority of tuberculous sero-fibrinous effusions are sterile; organisms are neither found on cover-slip preparations nor does anything grow in cultures. Our own experience is in accord with this, except that in one case the tubercle bacilli were definitely determined in the exudate. This was after repeated tappings. A sterile effusion is regarded as a point in favor of the tuberculous nature. In the purulent tuberculous exudates the bacteriological results are also variable. In some of the acute cases, as in one which I shall describe shortly, the bacilli of Koch were abundant. In other instances only pus organisms or the diplococci are present, or there may be no micro-organisms. A more important and more satisfactory test is the inoculation of the exudate into the peritoneal cavity of guinea-pigs, experiments which in the hands of some of the French observers have yielded positive results in the sero-fibrinous and purulent pleurisies of individuals apparently not tuberculous.

When Koch's tuberculin was in vogue, it was hoped that it might at any rate give us a means of positive diagnosis. The report of the German hospitals shows that in the subjects positively tuberculous the great proportion of them present reaction, whereas in suspected individuals about 60 per cent., and in non-tuberculous subjects only about 25 per cent. Subsequently, in speaking of diagnosis, I will narrate an instance in which the acute reaction to tuberculin led us into a serious error in diagnosis.

And lastly, the nature of the pleurisy may not be apparent for months or years, when the onset of a tuberculosis in other parts may indicate clearly the character of the whole process. You are all familiar with the striking statistics published of late years, none more interesting than those by Dr. Vincent Y. Bowditch from his father's records. Such statistics from private practice are of infinitely more value, as a rule, than those from hospitals. The time has been altogether too limited at the Johns Hopkins Hospital to determine, even if we could, the subsequent history of the great proportion of the cases of sero-fibrinous pleurisy which have been under treatment. It is interesting to note, however, in striking contrast to figures from some hospitals, that so far as our records go, only five of these patients have subsequently had tuberculosis. While our hospital figures are by no means in favor of the view that a large proportion of all sero-fibrinous pleurisies are of a tuberculous nature, I must confess that in private practice I have, year by year, been increasingly impressed by the frequency with which the subjects of pleurisy with effusion subsequently become tuberculous. Such cases as the following are not uncommon.

A few months ago I saw Dr. Martinet, a man aged forty, of fine physique and general good health, and excellent family history. In the summer of 1892 he developed, without obvious cause, pleurisy on the right side, and in this attack was seen on several occasions by Dr. W. S. Thayer. He was aspirated twice, and made a very satisfactory recovery, and resumed his work. Three months subsequently, he developed basilar meningitis, of which he died in three weeks. There was nothing in the condition of this patient or in the character of the pleurisy to justify the suggestion of a tuberculous nature; but the onset of a meningitis, which ran a long course like the tuberculous form, with strabismus, etc., rendered pretty clear the nature of the process. A very similar case, I remember, in the practice of my late colleague, Dr. Ross, of Montreal. A young man was admitted with pleurisy on the left side, and the history of having had a previous attack several months before. The effusion gradually diminished, but signs of local disease developed at the apex of the right lung. About three months after admission a purulent otitis media developed on the left side, followed shortly by meningeal symptoms, of which he died in the third week. The autopsy showed greatly thickened pleural membranes on the left side, many tubercles and local tuberculous disease at the right apex, with a tuberculous basilar meningitis.

I have seen recently a young man with an advanced pulmonary tuberculosis, who consulted me first in Philadelphia in October, 1888, when he had the left pleura full to the clavicle with a serous exudate. There is no tuberculous history in his family. The disease set in insidiously with cough. He was tapped but once, and he rapidly gained health and strength. I did not see him again professionally until the autumn of 1892, when he had had attacks of severe prostration and shortness of breath, but very little fever. Since then, signs of local disease have developed and extended, and tubercle bacilli are present in the expectoration. Cases such as these could be paralleled from the note-books of any physician in large practice. The cases from the wards which have developed pulmonary tuberculosis will be described later.

II. CLINICAL TYPES.

Tuberculous pleurisy may be part of a general miliary infection, but it is rare to find the pleuritic symptoms dominating, or even pronounced enough to attract attention. In reviewing any large number of cases, the character of the onset and the quick or slow course offer the most valuable features for classification, and separate two types, to which may be added a third, when the pleurisy forms part of a general serous membrane tuberculosis.

1. *Acute Tuberculous Pleurisy.*

It is difficult to say, in our present state of knowledge, the proportion of instances of acute sero-fibrinous pleurisy due to tuberculosis. The cases are rarely fatal; a large majority recover completely; in a few the condition becomes chronic; a variable number develop tuberculosis. More than this we cannot say, but clinical and anatomical study enables us to separate, at least, three groups of tuberculous cases in which the onset is acute.

(*a*) *Acute tuberculous pleurisy, with subsequent chronic course.*

There are cases of tuberculous pleurisy in which the disease sets in abruptly with pain in the side, fever, cough, and sometimes with a chill. There may be nothing whatever to suggest a tuberculous process; the subject may be of fine physique and of excellent family stock. Nor may there be anything in the course of the disease, at first, to excite suspicion. The effusion augments and the patient is tapped, perhaps repeatedly, and may get well with evidences of a greatly thickened pleura. Then the pleurisy may recur, and the case is labelled one of chronic pleurisy with thickening of the membranes, and finally the lung is infected, or tuberculosis of other parts becomes manifest. The following is a good illustrative case, of special value from the fact that the death occurred from an intercurrent affection, and we were able to study the condition of the pleura just about a year after the onset of the first illness.

CASE I. Pleurisy, with acute onset; chronic course of nearly a year's duration; repeated tappings; acute pneumonia; death; autopsy.

John A., aged forty-five, was admitted to ward F of the Johns Hopkins Hospital, June 18, 1892, complaining of shortness of breath, swelling of the feet and legs.

His mother and four or five of her sisters died of phthisis.

When young, had (he was told) scrofula, and had an operation performed on both hips; the wounds discharged for two years. He was not then, nor has been since, at all lame. Ten years ago he had hydrocele on the right side, which was tapped. After childhood he grew into a remarkably strong, powerful man. Previous to January, 1892, he had been working in the Belt-line tunnel for nine months, and was in perfect health, weighing 235 pounds. He went to Virginia, and while there, in January, his present illness began. While at work on a bridge he felt dizzy, had a severe pain in the left side, followed by cough, shortness of breath, much expectoration, which was not, however, blood-tinged. He went to a hospital in Washington, and was told he had typho-pneumonia. He had high fever, and was evidently very ill. The feet were swollen, and he had at times heavy sweats. He was several months in hospital, and was convalescent only about a month before his discharge on June 2d. He does not give a very clear account of his symptoms while in the hospital at Washington, but he had cough and pain in the side, and he lay principally on his right side. He lost also a great deal of weight.

Condition on admission (by Dr. Thayer). Patient is a large-framed, muscular, fairly well-nourished man. He is propped up in bed, inclining chiefly towards the left side. Lips and mucous membranes of good color; respirations rapid, 32; pulse, 128, regular, tension rather high; radial vessels are somewhat sclerosed. Temperature on admission, 99°; weight, 175 pounds.

Inspection. Thorax; the left side looks larger and movements are much restricted. The cardiac impulse is seen to the right of the sternum.

Percussion gives clear resonance in the right front as far as the third rib, where, close to the sternum, in the fourth and fifth interspaces, it becomes flat. On the left side there is modified resonance below the clavicle, shading into absolute flatness at the second rib, in the erect posture; at the third rib when recumbent. The flatness extends over the whole of the left back. Tactile fremitus is absent over the flat region, and the breath sounds are distant and tubular. On the right side they are clear, loud and breezy. The heart sounds are heard best to the right of the sternum, and are clear, the second loud and sharply accentuated.

Examination of the abdomen was negative. The urine was clear, yellow, acid, faint trace of albumin, no casts. The patient was aspirated, and 1,500 c. c. of a clear, yellow serum withdrawn.

For the first month in hospital the patient's condition did not materially improve. He lost in weight from 175 pounds to 157; the temperature range was constantly between 98.5° and 100°, rarely going to 100.5°, and only once, on the second day after his admission, reaching 101.5°. The fluid gradually reaccumulated, and he was tapped on the 21st, with a withdrawal of 1,280 c. c. of fluid; on the 30th, when 1,000 c. c. were withdrawn; and on July 8th, when 1,100 c. c. were removed. Early in July he began to improve — the appetite increased, and he gained in weight. On the third of August the following note was made: "The patient has been aspirated in all six times, the last time being on the 26th of July. On inspection, there is now very marked flattening of the left front. The expansion is greatest on the right side, on which percussion note is full and clear. On the left side there is flat tympany above the second

rib, below absolute flatness. Over the flat areas there is a distant, tubular breathing, of almost the same intensity everywhere. The vocal fremitus is diminished. The breath sounds very nearly absent in the supraspinous fossa." He was aspirated the seventh time on August the 3d, with removal of 800 c. c., and the eighth time on August 16th, when 600 c. c. were removed; the fluid of the last four tappings was blood-tinged. In the latter part of July and the first two weeks in August he improved rapidly and gained in weight, and on the 16th weighed 175 pounds.

The patient was discharged on August 18th, when the following note was made: "The left side of the chest seems somewhat sunken; right side expands fully and well, and looks large. At the left apex there is a flat tympany, which shades into flatness at the fifth rib, just outside the nipple line. At the left back there is a marked dulness, becoming absolute about an inch below the angle of scapula. Above this point the vocal fremitus is felt, below it is absent. Respiration is heard, though feebly, everywhere except at the extreme base. The point of maximum cardiac impulse is not to be made out; the sounds are heard distinctly over the normal area; the second pulmonic sound is accentuated."

The diagnosis of pleurisy with effusion was made. No suspicion was entertained by Dr. Thayer, under whose care he came during my absence, that the process was tuberculous; indeed, there was no evidence whatever to indicate this, except that the last four tappings were slightly blood-tinged.

November 30, 1892. Patient was re-admitted to-day, with dyspnœa, cough and fever. He states that he has remained well since discharged, August 18th, and has been working on the streets ever since. Three weeks ago he had slight shortness of breath after an unusual exertion, and ever since that has had slight cough, with white, frothy expectoration. He worked every day until November 26th. Last evening he had a heavy chill, in which he shook for an hour. This was followed by fever, which persisted all night. This morning he spat up a little blood. His appetite has been good.

Condition on admission. Weight is 170 pounds. Temperature, 100.4° at 2 P. M., rising to 103° at 4 P. M. He had a profuse sweat in the afternoon, and the temperature fell to 98° at six o'clock. Pulse ranged from 80 to 120; respirations from 18 to 36.

December 1st. This morning patient is lying on his back, face somewhat flushed, lips and mucous membranes and finger-tips somewhat cyanotic. Pulse 104, full, of fair tension. Respirations 32. There is marked flattening in the left side in front; the right side of the chest expands fully. Resonance throughout the right front and axilla, good. There is marked dulness over the left chest, resonance in front having a slight tympanitic quality. There is dulness everywhere over the left chest behind, shading into flatness below the middle of the scapula. On the right side behind, the resonance appeared good, and the respirations were clear. On the left side behind, the breathing was distant, tubular, and in the infrascapular region scarcely audible, vocal fremitus distinct. Dr. Hewetson put in a needle in the left back and obtained clear fluid.

Heart, well marked epigastric impulse. The maximum impulse cannot be made out. The sounds are the best heard in the fourth interspace, four centimetres from the sternum. The spleen is not palpable; liver not enlarged.

The sputum not very abundant, muco-purulent, blood tinged, contained a few distinct tubercle bacilli, and many encapsulated diplococci.

The urine, reddish brown, specific gravity 1,025, moderate amount of albumin, no tube casts.

December 3d. Within the past twenty-four hours the signs of consolidation have appeared in the right side, and have extended rapidly. This morning dulness begins at the third space in front, and is marked to the middle of the back behind. The breathing is of a modified, tubular character, and accompanied with fine crepitant râles. The temperature rose throughout December 1st, and between 6 A. M. and 4 P. M. of the 2d, was continuously between 105° and 106°. For the past twenty-four hours the range has been between 103° and 104°. The pulse range has been from 106 to 120. The cough has been very distressing. The sputum is rusty, brown, tenacious and contains tubercle bacilli. On the evening of to-day a moderate venesection was practised.

December 4th. The dulness has extended on the right side behind, and there is now tubular breathing from the spine of the scapula to the base; pulse is good; the temperature fell last evening to 101°; this morning it is high again, 104°. The respirations are about 40. There is marked leucocytosis, 33,000 white corpuscles per cubic millimetre. During the day, patient sank gradually, the pulse becoming feeble, in spite of the persistent administration of stimulants, ammonia, etc.; the temperature kept up, and he sank and died at 2 A. M.

Autopsy (Dr. Flexner). Body of a large-framed, well-nourished man. Peritoneum smooth. Thorax; universal adhesions, which were readily stripped off on the right side. On the left side, dense fibroid union of the layers of the pleura to a distance of about eight centimetres from the sternal margin. The heart much distended, with firm, gelatinous clots; moderate hypertrophy of the left ventricle, distinct hypertrophy of the right, the walls of which were firm and considerably thicker than normal. No endocarditis.

In removing the left lung, an encapsulated serous effusion was opened, occuping the layers of the pleura over the postero-lateral region of the left chest. The costal pleura was greatly thickened, ranging from one to one and one-half centimetres; at the diaphragm, it was in places as much as two centimetres in thickness. The visceral layer was also thickened, but not to the same degree, only from three to five millimetres. Both layers were smooth, grayish-white in color, in places presenting areas of congestion and hæmorrhage. There was a good deal of grayish-white gelatinous fibrin in places, closely adherent to the visceral pleura. There were no caseous masses, no spots of caseous infiltration on the surface of either layer. On section, the thickened pleura had the appearance and consistence of firm, new connective tissue, and at first sight it seemed as if the process were really a simple, chronic pleurisy, more particularly as no miliary tubercles were noticed on the surface, and no caseous masses. On close examination, however, of the cut sections, particularly in places, grayish, translucent, fibroid tubercles could be seen projecting above the cut surfaces. These were particularly marked in the thickened diaphragmatic layers. At one or two spots there were found small areas, from three to five milli-

metres in extent, of grayish, yellow, tuberculous infiltration. The left lung was very considerably compressed, but still it everywhere contained air, except at the extreme base. There were no miliary tubercles, no caseous masses. The right lung was large, voluminous, retained its shape, did not collapse and was everywhere airless, except at the extreme apex and the antero-lateral margin. The pleura was a little thickened and covered with tags of old adhesions; no tubercles were seen. On section there was at the apex an area of caseation and softening the size of a walnut, surrounded with tubercles and smaller areas of caseation. This communicated directly with a good-sized bronchus. The lower part of the upper lobe, the greater part of the middle lobe, and all of the lower lobe, were in a condition of red hepatization. There were no miliary tubercles, no caseation. The bronchial and tracheal glands were greatly swollen, tumefied and presented here and there small caseous masses. There was nothing of special note in the abdominal organs; no tubercles. In the right testicle there was a fibroid and cartilaginous, cyst-like structure containing cholesterin.

There was a marked tuberculous history in the patient's family, and the latter tappings were blood tinged, points upon which in a less robustly built man, we would doubtless have laid greater stress. On his return with an acute pneumonia, tubercle bacilli, as well as pneumococci, were found in the sputum, and the former gave us, for the first time, a definite clue to the nature of the pleurisy, now chronic, but in process of healing. It is interesting to note that the tubercle bacilli came from a very small focus of caseation and softening in communication with a bronchus.

(To be continued.)

ABDOMINAL HYSTERECTOMY FOR FIBROIDS, WITH CASES.[1]

BY J. W. ELLIOT, M.D.

THE indications for operating on fibroids generally agreed on by the best men of the day are:

(1) Hæmorrhage.
(2) Pain.
(3) Large size of the tumor.
(4) Rapid growth.
(5) Pressure symptoms, especially of bladder and ureters.
(6) Presence of ascitic fluid.

To just what extent any of these symptoms must be present, to call for an operation, is an open question. With considerable pain, for instance, in a medium-sized tumor growing slowly, some men would operate much earlier than others. There are two important sides to this question which, considered separately and in relation to each other, will, I am sure, improve our judgment in this matter.

First, Can these symptoms be controlled? If not, to what do they lead?

Second, How successful is the operation? When is it most successful? When is it least successful and most fatal?

As to controlling the symptoms; hæmorrhage is the one symptom that has been most successfully treated by palliative measures. Curetting, ergot and galvanism have proved useful, and should be tried when the tumor is small. But these remedies are usually only partially successful, and are not without danger. The cause is still present, and will soon reassert itself. If the palliative treatment is unsuccessfully persisted in a little too long, the patient comes to operation anæmic and debilitated, and must, therefore, be transferred into a class of less favorable operations. Whatever good has come from electricity in these cases, we know also of a great amount of harm. Patients have told me that they did not suffer as much from the operation as they did after each application of electricity. I have seen peritonitis follow this treatment, and we are all familiar with the reported cases of septicæmia from the same cause. Many operators have complained of the adhesions found when patients who have been treated by galvanism come to operation.

Pain has sometimes been relieved by galvanism, but it is usually due either to contractions of the uterus, or to pressure on the pelvic nerves or other organs, in which case no palliative treatment could be advised. Large size, rapid growth and pressure symptoms evidently cannot be relieved.

Thus we see that with the exception of hæmorrhage, and that not very certainly, the symptoms indicating the operation cannot be relieved. If not relieved, they usually lead to slow death, or to a hopeless invalidism. Beside these symptoms, there are other more treacherous complications which lead in the same direction. The tumors often become malignant. They break down and suppurate inside. Their presence causes dangerous diseases of the Fallopian tubes, and other complications difficult to recognize without operation, on account of the prominence of the tumor itself. It is not at all unheard of for the blood, or other discharge from the tumor, to become infected and to cause a fatal septicæmia. I have just seen, in consultation, a very sad case of such an accident. Curetting a very large, irregular uterine cavity already filled with germs, or plugging such a cavity with a vaginal tampon, is evidently not devoid of danger.

Now, as to the other side of the question; for the more successful the operation, the earlier we should advise it.

Statistics are so misleading that no one can say exactly what the mortality of this operation is. But we know that is much lower in the last five years. Thornton, Bantock, Meredith and others have been having very good results of late, also men in our own country, so I think it is fair to infer from the late reports that the mortality of the best operators is below ten per cent. This is such an improvement on the thirty-per-cent. mortality, which pertained ten years ago, that we must reconsider our point of view, and advise the operation earlier and oftener.

The operation is most favorable, when the tumor is small, and the health has not been seriously affected by the hæmorrhage, pain, etc. The operation is least successful when the tumor is very large, for then the operation is most severe, and the patient, debilitated by the long standing disease, is least able to stand it.

From all this, and my own favorable experiences, having had eleven operations with one death, and that in a large tumor of long standing, I have decided to advise the operation as soon as any of the above symptoms can be said to have become persistent. If the

[1] Read before the Suffolk District Medical Society, April 29, 1893.

tumor is small, I should first remove the ovaries (I have also had several very favorable results from this operation), but if it is as large as a cocoanut, and any of the symptoms above mentioned are persistent, I do not advise curetting or removal of the ovaries, but hysterectomy, because the tumor, already too large to carry with comfort and safety, will, in all probability, increase in size.

As to the method of doing the operation: it depends wholly on the size and position of the tumor and the strength of the patient. I have never had a death from the extra-peritoneal treatment of the pedicle with a wire or rubber ligature. I am sure that in a large tumor in a debilitated patient it is the best operation, for it is much the quickest and least severe of all the operations. Such patients may die of shock, if the operation is too severe, but they are used to the torture of the tumor and can stand the extra-peritoneal treatment of the stump with patience. The operation advocated by Kelly, that of sewing the stump together and then fastening it into the abdominal wound seems to me less advisable than simply sewing the open stump into the abdominal wound. This I have done with a good result. It has the advantage of taking the open uterine canal out of the abdominal cavity and placing it where it can be dressed with gauze. Convalescence is quite as short as in any of the other operations. It is disappointing to find that convalescence is not materially shortened by these newer operations; for when the stump is sewed into the abdominal wound it usually suppurates and takes about as long to heal as when it is crushed in the ecraseur. Bear's operation seems to me a good one, if it will give good results, which remains to be seen. In the only case of mine that died, I was trying to do his operation. It was a severe and complicated case, and I am sure it would have been better to do that particular case with an ecraseur. I do not favor taking out the cervix except for cancer as it weakens the pelvic floor.

HYSTERECTOMY FOR FIBROIDS: CASES.

CASE I. The patient, a single woman, thirty-seven years old, was sent to me by Dr. Johnson. She had first noticed the tumor in the abdomen fourteen months before I saw her. It had grown rapidly, and was then causing her so much pain that she found it difficult to continue her occupation as a weaver in a mill. She was much reduced in strength, and was annoyed by frequent micturition. Menstruation was not excessive.

The tumor was indistinctly fluctuating, and seemed to move independent of the uterus. The diagnosis was doubtful.

The operation was done November 5, 1886, at the Free Hospital for Women. The tumor was delivered through an incision from symphysis pubis to umbilicus. It proved to be a general fibroid enlargement of the fundus, with a long, narrow cervix. The broad ligaments were tied, and the pedicle, consisting of a small cervix uteri, was held in a wire ecraseur, and treated extra-peritoneally. The ovaries were not removed. The peritoneum was stitched to the stump below the wire. There was a good deal of shock. The temperature rose to 102°, but fell to normal on the third day. The stump was dressed with iodoform gauze, and was not looked at for six days, when it was found to be dry and hard. The wound healed by first intention, and the wire was removed on the fourteenth day. The patient was up and about at the end of a month.

The specimen weighed four pounds, and was a general fibroid enlargement of the uterus, with four inches of uterine cavity, which was large enough to admit two fingers. It contained many dilated lymph-spaces, and large blood-vessels, which had given it a semi-solid feel.

Six months later, the patient was seen and found in good condition. She had resumed her work in the mill, but complained of hot flashes and other discomforts which usually occur at the change of life.

CASE II. The patient was a negress, age thirty. She had been well until one year before I saw her, when she noticed a small lump in the lower abdomen, about as large as an orange. This had steadily increased in size, and was then three inches above the umbilicus. Nine months before I saw her, she began to flow much more than usual; later the flow came three or four times in the month; at last it became continuous and profuse. She had frequent micturition, but no pain, except a dragging feeling and a sensation of weight. She had become short of breath, and was beginning to be troubled by hæmorrhoids. She was well nourished, but the mucous membranes were pale. She had a systolic heart-murmur at both base and apex, with accentuation of the second pulmonic. The tumor was firm and irregular in shape, and moved with the cervix.

The operation was done June 5, 1888, at the Massachusetts General Hospital. The tumor was delivered through a four and a half inch incision. The broad ligaments were tied off, and the pedicle, consisting of an enlarged cervix uteri, was held in a wire ecraseur, and treated extra-peritoneally. The Fallopian tubes were greatly dilated (about two inches in diameter), and bound tightly to the ovaries, which could not be removed. The peritoneum was stitched to the pedicle below the wire. A drainage-tube was placed in the pelvis, behind the stump. The stump was dressed with iodoform gauze, and was not examined until the fifth day, when it was found dry. The drainage-tube was removed on the second day. The patient made a slow recovery. On June 24th, a fluctuating mass was detected in Douglas's fossa. This was aspirated, and proved to be the remains of the dilated Fallopian tubes, which had refilled with clear fluid. July 2d, this was laid open, and drained through the posterior vaginal cul-de-sac.

The patient was discharged well, July 24th, seven weeks after the operation.

CASE III. The patient, a single woman of thirty-nine years, was referred to me by Dr. Fifield, of Dorchester, who had found a fibroid tumor the size of an egg two years previous. She was unable to walk, and had great trouble with the bladder. At times, was unable to hold her water; at others, she passed it every twenty minutes. Micturition was difficult and painful. She suffered a great deal of pain, was unable to work, and therefore could not support herself. There was partial obstruction of the bowels. The catamenia were regular and not profuse, but very painful. A hard tumor was found, extending nearly up to the umbilicus. It evidently grew from the posterior uterine wall, and extended deep into Douglas's fossa. The operation was done May 20, 1890, at a private hospital, assisted by Dr. A. K. Stone. The tumor was found to be a fibroid as large as a child's head, growing in the posterior uterine wall. The uterus and fibroid were so locked in the pelvis that

it was absolutely impossible to lift the mass out of the pelvis. The ovarian arteries were then tied, and the capsule of the fibroid was split over its top and posterior surface. The tumor was enucleated from the posterior wall of the much-enlarged uterus, leaving a ragged hole from fundus to cervix. An attempt to close this cavity with stitches was given up on account of the critical condition of the patient. The whole uterus was then drawn up and enclosed in a wire ecraseur and amputated low down on the cervix. The stump was treated extra-peritoneally.

The operation was severe, and caused much shock, but the patient soon rallied. The temperature rose to 100°. The wound was dressed on the sixth day, for the first time, when it was found moist and sloughy. The wire was cut on the tenth day. The stump sloughed, and discharged pus freely. On the eleventh day, the patient was doing well; but at 2 A. M. she sat up in bed, bathed in perspiration, and gasping for breath, called the nurse to open windows. The pulse became imperceptible, and she was thought to be dying. With stimulants and digitalis, this critical condition passed. The next day, the pulse was very rapid, and the temperature was subnormal. This attack must have been embolism in the lung. She gradually gained strength, and was discharged at the end of six weeks. September 19, 1890, the patient was much improved in general health. The cervix uteri was found to be free from the abdominal wall.

May 21st, she had had whooping-cough for nearly three months. This cough had caused a hernia at the point where the stump had been attached to the abdominal wall. It was controlled perfectly by an abdominal bandage.

CASE IV. The patient, thirty-six years old, had been married twelve years; had had one child, and one miscarriage. She had had profuse and constant flowing, also pain and vomiting at each menstruation. She had had two attacks of peritonitis; had been confined to her bed for several months the year before, and had, when I saw her, been in bed for thirteen weeks. An enlargement of the abdomen, beginning eight years before, had increased steadily ever since. She was unable to attend to household duties, and desired to have the tumor removed.

Examination showed a hard, rounded tumor, the size of a child's head, just above the pubes, freely movable and not tender. The sound passed two and one-half inches. There was a trace of albumen in urine.

The operation was done September 18, 1891, at the Massachusetts General Hospital. The bladder was dissected from the tumor in front, and a wire ecraseur was passed around the cervix, which formed the pedicle, and was treated extra-peritoneally. The tumor weighed four and one-half pounds. The patient recovered well from the operation. On the following day, there was a smart hæmorrhage from the stump, which was controlled by tightening the wire.

The wire was removed on the sixteenth day. The patient went home well in seven and one-half weeks.

CASE V. The patient was a widow, age thirty-seven, having no children. She first noticed an enlargement of the abdomen eight months before I saw her; since then it had gradually increased in size. About the same time, she flowed for four weeks steadily, having three or four severe hæmorrhages during that time. Since then menstruation had been very profuse. When I saw her, she was very white, and looked sick. Her temperature varied from 100° to 101°.

The tumor was a hard, rounded mass, rising from the pelvis to near the umbilicus, appearing about as large as a man's head. The cervix was small, and moved with palpation of the tumor, being evidently in intimate connection with it.

The operation was at the Massachusetts General Hospital, September 26, 1891. The tumor was delivered by a seven-inch abdominal incision. The broad ligaments being tied off, and the bladder dissected away, a wire ecraseur was slipped over the tumor. The cervix formed the pedicle, and was treated extra-peritoneally. The wire broke, in tightening on the fourth day. The patient made an uninterrupted recovery, and was discharged in five weeks, with a small sinus still unhealed.

CASE VI. The patient, a single woman, of forty-four years, suffered from profuse flowing. The abdomen had been enlarged for four years. She had had difficult micturition for one year. She suffered principally from the size of the tumor.

The abdomen was found to be greatly enlarged. The tumor was elastic, but not fluctuating; was fairly movable, and seemed not connected with the uterus.

Operation, January 18, 1892, at the Massachusetts General Hospital. The incision extended from the pubes to the ensiform cartilage. The tumor was very large, and grew from the fundus uteri. A large part of its blood supply came from the mesentery. The mesentery had evidently become attached to the top of the tumor, and had itself disappeared, leaving a large plexus of arteries and veins to nourish the tumor. Thirty or forty vessels as large as a lead pencil were tied off: the broad ligaments contained very large vessels, and were tied off. The uterine arteries were tied, and the tumor cut away. The pedicle was then sewed into the abdominal wound, and a glass drain placed in the pelvis. The tumor was found to have begun to break down, and was sloughing in the centre.

The wound healed by first intention, except where the stump was sewed in; this suppurated, and did not heal until March 5th, a little over six weeks. The patient was greatly relieved by the operation, and gained forty pounds in the next year.

CASE VII. The patient, a single woman of twenty-seven years, entered the Massachusetts General Hospital in February, 1892, under Dr. J. C. Warren. She was very anæmic and listless, and was flowing profusely. He removed a uterine polyp, with great relief to her. At the operation, he noticed that there were other fibroids present, and one of them quite large. She reentered the hospital September 22d, having been married in the meantime. Ten days before entrance, she had had a miscarriage at three months, which was followed by much flowing and great weakness, loss of appetite, foul vaginal discharge, and a very bad look. She was blanched and weak, and seemed to be mildly septic. The tumor had grown rapidly of late.

Just above the pubes was a large tumor, and several smaller ones, the mass being larger than a cocoanut. The tumor was hard, movable, but tender on pressure. The cervix was patulous, and seemed to be filled with a broken down polypus. The diagnosis was of suppurating fibroid. Hysterectomy was determined on, because there were numerous fibroids, and it was

thought that any palliative operation would be quite as dangerous.

The operation was done September 27, 1892. The patient was in the Trendelenburg position. The broad ligaments were tied off. The bladder was then dissected off the tumor, a temporary rubber ligature was passed around the cervix, and the tumor was cut away. The cervical canal was then cut out, and the sides of the cervix sewed together. These stitches were left long, and by them the stump was held up and sewed into the abdominal incision, silk-worm gut sutures being passed through the abdominal walls and the stump.

There was no shock. The temperature rose to 101.5°. The wound healed by first intention, except where the stump was sewed in. This part suppurated freely, and had to be packed with gauze for several weeks. The wound nearly healed in three and one-half weeks, and the patient went home five weeks after the operation. The tumor consisted of a uterus much enlarged by several fibroids. In the uterine canal was part of a placenta in a putrid condition.

CASE VIII. The patient, a married woman thirty-nine years old, was sent to me by Dr. Comey, of Clinton. She had had no children or miscarriage. Two years previous, she had had a very severe uterine hæmorrhage, and was curetted. For six months, the flow was moderately profuse. Then, it gradually increased, and continued for three months at a time. Of late, it had been irregular, but very profuse and debilitating, keeping the patient in bed. The patient had become very anæmic, and blanched and nervous.

The tumor was a general enlargement of the uterus, and about the size of two fists, the uterine cavity being five inches deep.

The operation was done October 29, 1892, at a private hospital. Patient in Trendelenburg position. The abdominal incision was five inches long. The broad ligaments were tied off, and the bladder dissected away. The wire ecraseur was placed on the cervix as a pedicle, which was treated extra-peritoneally.

The patient made an uninterrupted recovery. Temperature rose to 100°. The wire was removed on the next day. She was up and about in three and one-half weeks, and went home in less than five weeks.

Soon after her return home, she became very nervous, and developed an attack of melancholia, from which she has recovered.

CASE IX. The patient was single, and forty years old. She was brought to me by Dr. Tuck. She had been treated for a fibroid by electricity for two years. The tumor had grown much larger in the last six months, and the patient had lost strength and flesh. She suffered pain while standing. The catamenia were profuse and painful. Both legs were œdematous. The patient was becoming incapacitated for work. The tumor was evidently solid, and filled the entire abdomen, extending deep into Douglas's fossa.

The operation was done on December 14, 1892, at a private hospital. The incision extended to the ensiform cartilage. The tumor was nearly as large as a pregnancy at full term, the veins in the broad ligaments were as large as two thumbs, and the uterine arteries were larger than a lead pencil. The broad ligaments were tied off, each vessel being tied singly. The ovarian and uterine arteries being tied, the tumor was shelled out of its capsule, which dipped deep into Douglas's fossa. The uterus was amputated at the cervix. The capsule left by the tumor was a large, ragged, bleeding hole behind the uterus, and was stitched to the abdominal wall in such a manner as to close the peritoneal cavity above, and to leave the bed of the tumor open to the outside below; the cervix stump was in this lower cavity. This whole space was then stuffed with gauze. The bleeding was profuse, and the patient was in collapse at the end of the operation. In the evening, the condition was worse, and it then became evident that hæmorrhage was going on. Probably some ligature had slipped off of a large vessel. The patient was evidently too feeble to have the abdomen reopened, and died. This case should have been operated on much earlier and it shows the result to continuing useless palliative treatment.

CASE X. The patient was brought to me by Dr. Straus, of Manchester. She was a single woman, and thirty-seven years old. She complained of pain on the right side, which was increased in walking. She also suffered from painful and frequent micturition. She had lost flesh and strength in the last year. She had just recovered from an attack of peritonitis, which had lasted nine weeks.

On examination, a hard, nodular tumor, about as large as two fists, was found between the fundus of the uterus and the bladder. It was thought that this tumor had caused the recent attack of peritonitis, and operation was therefore advised.

The operation was done at a private hospital, February 22, 1893. The fundus uteri was found covered with small fibroids, varying from the size of a walnut to that of a marble. There were at least twenty different nodules. The bladder was adherent to uterus by false membranes. The broad ligament being tied off, and the bladder dissected free, a wire ecraseur was passed around the cervix, which made a pedicle, and was treated extra-peritoneally. The operation was accomplished without delay, and there was no shock. The wire was never tightened, and the first dressing was done on the sixth day. The wire was removed on the eighth day. On the tenth day, while cutting away a slough from the stump, I cut a good-sized vessel, which spurted hard enough to hit me in the face. I was much alarmed, and thought I had cut the uterine artery, and tried in vain to catch it with forceps. Finally, the bleeding was stopped by pressure with absorbent cotton.

The patient made an excellent recovery, and went home in five weeks, well. Although the part of the cervix inclosed in the wire was crushed, yet little or no pus was seen during the whole convalescence.

CASE XI. The patient, a married woman forty-four years old, was sent to me by Dr. S. W. Torrey, of Beverly. She first noticed the tumor ten years ago. Catamenia had always been profuse, and had increased during the last year. She suffered constant pain on the right side, and had lost much flesh during the last year, and had become pale, nervous and sleepless. She looked like a very sick woman.

A solid tumor extended to umbilicus, and moved with the cervix.

The operation was done, March 2, 1893, at Dr. Torrey's hospital in Beverly. The patient was in the Trendelenburg position. The tumor proved to be a fibroid, about the size of a five months' pregnant uterus. There were several small tumors growing from the large one. One tumor, about the size of an egg, had become embedded in the abdominal wall,

and was so bound by inflammatory products as to require a very difficult dissection for its removal. Another nodule had become encircled by a cord of intestine; the two were so firmly adherent that it was impossible to dissect them apart without injuring the intestine; so the tumor was sliced off, leaving a portion attached to the intestine. The bladder was dissected from the large tumor, and a rubber ligature was passed around the cervix uteri, which formed a large pedicle and was treated extra-peritoneally. A small, multilocular cyst was found, firmly imbedded in the broad ligament. This was laid open, and drained. The ovaries were not removed.

The patient made a rapid recovery. The temperature and pulse remained normal. The stump was first dressed on the eighth day; the wound healed by first intention. Dr. Torrey removed the rubber ligature on the twelfth day. There was considerable sloughing and pus about the pedicle, but it granulated rapidly. The patient returned to her home on April 5th, one month after the operation, with a granulating pedicle wound. She had some sleepless nights and mental disturbances, which gave rise to anxiety for a time; but this passed off, and may have been due to iodoform gauze dressing. April 18th, six weeks after the operation, the patient was up and about.

The above are not selected cases, but include all the cases I have ever done.

HOW SHOULD THE GENERAL PRACTITIONER DEAL WITH STRANGULATED HERNIA?[1]

BY ARPAD G. GERSTER, M.D.,
Professor of Surgery in the New York Polyclinic, Surgeon to the German and Mt. Sinai Hospitals, New York.

THE cardinal condition for the successful treatment of strangulated hernia is an early diagnosis. I wish to call attention to the frequency with which, during the prevalence of gastro-intestinal disturbances in the summer months, the presence of a strangulated hernia escapes the notice of the overworked practitioner. Within my own experience a number of such cases have occurred where the suspicion of intestinal obstruction first arose on the appearance of fæcal vomit. Indeed, the rule to examine the groin, during any intestinal disturbance associated with persistent vomiting, should be invariable. The presence of diarrhœal or solid stools should not militate against this rule, as we know that strangulation of a hernia will frequently occur during the progress of an enteritis. I have also seen fatal errors committed by the mistaking of a small, incomplete, but strangulated hernia for a mass of inflamed lymph-nodes. Finally, I remember the case of a young man suffering from recent gonorrhœa, who, while vigorously rowing, slipped and fell backward into the boat. He instantly noticed a severe pain, which he referred to one of his testicles. The family physician found an intumescence of the scrotum, and unhesitatingly diagnosticated orchitis. Unfortunately this diagnosis was insisted on for five days, in spite of the grave and unusual symptoms which accompanied this supposed orchitis. When fæcal vomiting had set in, herniotomy was performed. The gut was found to be gangrenous, and the boy died. In the presence of any tumor of the localities where herniæ are wont to appear, whenever persistent vomiting occurs, the benefit of the doubt should be given to the assumption of hernia. In those cases where the physical characteristics of hernia are uncertain, an exact diagnosis should be arrived at even at the cost of a probatory incision.

It would transcend the limits of a brief paper to discuss all the methods which have been successfully used for the reduction of strangulated hernia; but so much may be said, that in the same ratio as the safety of herniotomy has increased, have the limits of permissible taxis decreased.

In attempting taxis we must observe, that unless the patient can manage to be perfectly passive, general anæsthesia should be employed. The longer the strangulation has existed, the more unlikely it is that favorable conditions will be present. Local inflammation will have set in, rendering the patient intolerant of manipulation; and the presence of a more or less copious effusion in the sac will rob the operator of the chance of manipulating the gut itself, the effusion acting as an interposed elastic cushion. To replace the protruding gut our efforts should be directed towards the neck of the hernia.

The patient's posture is also important. Elevation of the pelvis will be useful. Another expedient may be mentioned by which I have prepared a strangulated hernia for reduction. I mean the application of intense cold in form of an ice-bag, or the evaporation of ether poured on the swelling, drop by drop. The local pain is markedly reduced, the intumescent parts shrink, and reduction often becomes astonishingly easy. Force should never be employed, as it will not accomplish replacement, but will often, especially when strangulation has for some time existed, result in serious damage to the gut. A case in point is that of a young man who contracted hernia, which immediately became strangulated. The physician in charge attempted taxis five hours after the occurrence. So much force was used, that when I saw the patient six hours later, the scrotum, penis and groin were extensively ecchymosed. On herniotomy it was found that the peritoneal covering of the strangulated gut had been ruptured and stripped up for a considerable distance. The convexity of the viscus was necrosed, and an artificial anus was established. The man died of septic peritonitis. Another adjuvant of reduction is the hypodermatic use of morphine which, however, should be employed sparingly and with discrimination and only as a preparatory measure for taxis. Otherwise it is apt to mask the more salient symptoms of strangulation, lull patient and physician into a false sense of security, and lead to incalculable mischief.

Permit me to call your attention to a point of great importance in estimating the urgency of a given case. Recently acquired and especially femoral herniæ are often characterized by great intensity of symptoms, mostly due to particularly firm constriction or strangulation. In these cases severe local pain is the rule, vomiting is incessant, and projectile, remissions are few or absent, and all the characteristics of the disturbance are decidedly *progressive*. The integrity of the gut as well as the resisting power of the patient are rapidly being undermined, and immediate relief is imperative.

To point out the contrast I shall mention a type of strangulation which is at first comparatively mild, and where the term "strangulation" is not strictly appli-

[1] Read before the Surgical Section of the Massachusetts Medical Society, June 13, 1893, and recommended for publication by the Society.

cable, as the stenosis of the viscus is usually due to sharp flexion on account of the repletion of the prolapsed gut with liquid or solid contents. Here the tumor is not so acutely painful as in the former class, vomiting is infrequent, intervals of several hours (up to twelve) occurring, the length of remission depending on the amount of food ingested. Ultimately a hernia of this kind will lead to general exhaustion and gangrene of the intestine, though the progress of the malady is much slower. Aside from gut I have found strangulated herniæ containing (twice) a gangrenous vermiform appendix, the ovary, an infantile uterus, a diverticulum of the bladder, and in one instance, imbedded in an abscess, a foreign body (a fish-bone), which had apparently perforated the intestine of the hernia prior to strangulation.

A safe and well-tested working rule in dealing with strangulated herniæ of recent occurrence is to attempt gentle taxis; should this not succeed, to propose to the patient taxis in anæsthesia with the proviso, that if this miscarry, herniotomy should be immediately performed. Before anæsthetizing, everything should be prepared for the operation in order to save time and to save the patient a second narcosis. In the presence of fæcal vomiting it is desirable to empty the stomach by gastric syphon before anæsthesia; otherwise the putrid matter vomited during operation may enter the air-passages, causing suffocation or septic pneumonia.

The choice of the anæsthetic will also deserve some attention, chloroform deserving the preference, especially where pulmonary or renal disease coexists; ether, on the other hand, being preferable in the presence of cardiac weakness. Where the patient is very much exhausted it might be found advantageous to eschew general anæsthesia, and to perform the operation under cocaine, ether spray, or even without local anæsthesia.

There are on record a certain number of cases of successful taxis in which the reduction of the strangulated gut was undeniably made possible by preceding puncture and evacuation of liquid fæces. I have never consciously employed this treatment, deeming it more hazardous than a well-performed herniotomy.

As regards the technique of herniotomy, I do not propose to dwell upon the minute details of the procedure, and shall content myself with emphasizing two points, the observance of which goes far in rendering the operation successful. The first of these points is the observance of the ***strictest cleanliness*** or ***asepsis.*** Difficult as asepsis is where the abdominal cavity is invaded, it is rendered much easier by the topographical peculiarities of a wound in this region, as long as the gut is not gangrenous. The operation is practically extra-peritoneal, and infection must be gross indeed to result in peritonitis. Careful shaving of all the pubic hair, a thorough scrubbing with soap and water, followed by rinsing with a strong solution of corrosive sublimate of the entire field of operation, are conditions easily fulfilled. Instruments and dressings, the latter consisting of any available textile fabric, can be promptly sterilized *ex tempore* by a short boiling in a watery solution of washing soda. The vessels found in any kitchen will answer perfectly. For sponges wads of absorbent cotton or of the dressing material can be used. The towels to be employed about the field of operation should also be subjected to a similar boiling. I may safely express the opinion, that a thorough scrubbing of the surgeon's hands with soap and brush in hot water, followed by careful scraping of the nails and a short immersion in a mercurial solution, will insure a very efficient degree of asepsis.

As to the incision, I have to say only, that it should be ample, the upper angle of the wound extending well above the inguinal ring. Bleeding vessels should be promptly tied, and the sac cautiously opened at a place where fluctuation is apparent. This precaution will insure against wounding adherent gut. The sac should be split well up to its neck and then the contents should be carefully examined *in situ.* Should gangrene not be present in the visible intestine it may still exist at the site of constriction. To permit of a safe inspection of the constricted part of the viscus the constriction must be relieved not by blunt attempts at liberation but by *dissection from without inward*, this being the second point to be emphasized. The old and classical method of dividing the constricting fibres from within outward under the guidance of either a finger-nail or a grooved director is dangerous, especially where the gut has been irremediably damaged by prolonged strangulation. A much safer procedure is the division of all confining fibres by the knife, wielded under the guidance of the eye. Injury to an abnormal epigastric artery will thus be easily avoided, or, should it be unavoidable, the vessel can be readily secured. As soon as the strangulation is relieved *and not before*, the gut can be gently withdrawn and examined; should it be found healthy it can be immediately replaced. If its appearance is doubtful a fillet of silk can be drawn through the mesentery and the wound covered with a wet dressing. Within six hours an examination should be made, and if the gut is then found healthy, it may be replaced. If gangrene is undoubtedly present and fæcal vomiting or other urgent symptoms do not compel the establishment of an artificial anus, the intestine should be left unopened. Often the gangrene is very limited; and in these cases the gangrenous area can be inverted, and the healthy visceral peritoneum brought together over it by a longitudinal row of Lembert sutures. Should it become necessary to establish an artificial anus, two things must be carefully seen to. First that the last trace of constriction has been relieved, and, secondly, that a dam consisting of a light packing of iodoform gauze, slipped into the peritoneal cavity around the gut, corresponding to the neck of the hernia, should prevent the influx of fæcal matter.

It would transcend the limits of this paper to discuss the question, "When should an excision of gangrenous gut be practised, followed by intestinal suture?" or, "When shall the establishment of an artificial anus receive the preference?" Furthermore, I will abstain from considering when and how a radical closure of the inguinal canal should follow herniotomy. In concluding these desultory remarks I shall say:

(1) In case of uncertainty give the benefit of the doubt to the assumption that an obscure tumor of the groin is a hernia.

(2) Be gentle in attempting taxis, and do not spend too much time over it.

(3) Be thoroughly aseptic in herniotomy, and divide the constricting bands freely, not with the probe-pointed knife cutting from within outward, but with the scalpel under the guidance of the eye, from without inward.

THE oldest man in Kentucky died July 9th. He was born in Virginia in 1776.

A METHOD FOR APPLYING PRESSURE TO THE SEAT OF A FRACTURE FOR THE PURPOSE OF BRINGING THE BONY FRAGMENTS INTO ACCURATE APPOSITION AND RETAINING THEM THERE UNTIL CONSOLIDATION HAS TAKEN PLACE.

BY GEORGE H. MONKS, M.D.,
Surgeon to Out-Patients at the Boston City Hospital.

ON January 25th, L. P. H., a strong and well-built man, 35 years of age, applied at the Surgical Out-Patient Department of the City Hospital for treatment of an injury to the right forearm, sustained two days previously. An examination revealed fracture of the radius, near the middle of the bone. There was anterior displacement of the proximal fragment and posterior displacement of the distal.

On manipulation free mobility of the fragments, and bony crepitus were marked. There was considerable difficulty in keeping the fragments in position, — a circumstance probably due to the small size of the bone at this point and its depth from the surface.

Pads were carefully applied upon the arm, — one in front and one behind the fracture; and while extension was made upon the hand, a plaster-of-Paris bandage was put on over the pads, and reaching from the roots of the fingers to the bend of the elbow. At the end of six days this bandage was removed with great care and the seat of fracture gently examined. The fragments were found out of place, as before, and there had been no apparent attempt at union. Fresh pads with anterior and posterior wooden splints were then applied, only to be removed again within twenty-four hours on account of pain caused by the pressure which it was necessary to exert upon the pads, in order to keep the fragments together.

While I was holding the fragments in place with my thumbs and fingers, and was considering what means, yet untried, would be most effective in keeping this troublesome fracture permanently reduced, I was struck with the ease with which the parts could be held in perfect apposition by the thumbs and forefingers alone, and I said to my assistants, Mr. S. Y. Wynne and Mr. A. B. Duel, that, undoubtedly, the best appliance for this case would be one in which a pressure could be brought to bear on the seat of fracture, as nearly like that exerted by digital pressure as possible.

That same day these gentlemen suggested a plan which they put into service in this case with the most satisfactory results, and it is for the purpose of calling attention to this method of theirs that I report its trial.

A turn of bandage was loosely placed about the arm at the seat of fracture, and its upper end was then held by an assistant vertically upwards, the arm being horizontal. This served as a landmark to the fracture. With his other hand the assistant made extension by gently pulling on the hand of the patient. The hand and forearm were then wrapped in a layer of sheet wadding, and a light plaster-of-Paris bandage applied. While the plaster was still soft, pressure was made at the seat of fracture with the thumbs and fingers, as is shown in Fig. 1, the forearm being kept slightly supinated. Under this pressure, which was very slowly and gently applied, the fragments which, up to this time had been out of place, could be felt to slide back into proper position. The pressure was kept up until the plaster had hardened, when the digital depression was, of course, permanent. (Fig. 1.)

FIGURE I.

The pilot-bandage was then cut away, and the patient, who declared that his arm was more comfortable than it ever had been since the date of fracture, was sent home with his arm in a sling, and told to report the next day.

When he returned a fenestra was cut in the bandage, as shown in Figs. 2 and 3. This was done for the purpose of allowing inspection from time to time of the region of the fracture.

The pressure exerted by the depressions in the plaster appeared to have had no effect whatever in stopping the circulation of the parts, and the fragments seemed to be in perfect apposition. (Figs. 2 and 3.)

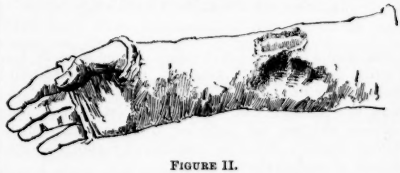

FIGURE II.

Twenty-one days after the plaster had been applied it was carefully removed and the union found to be firm and the apposition of fragments apparently exact. There was a narrow annular callus about the seat of the fracture. The plaster was re-applied, as a precautionary measure, and, in a short time, again removed,

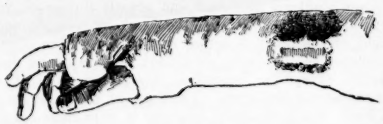

FIGURE III.

and the patient directed to use the hand. Improvement continued, and the result was in all particulars, satisfactory.

[1] Read before the Suffolk District Medical Society, April 29, 1893.

I knew that the bone would probably have united readily enough under the old form of treatment, but with these hitherto uncontrollable fragments held in exact apposition by the depression in the plaster, I felt sure that the union would be accomplished with the minimum of deformity and the result, as it proved, justified my expectation.

This same method of using the depressed plaster, instead of pads was employed with excellent results in two cases of Colles' fracture at the Hospital; but, as this is a fracture which, after impaction has been broken up, is usually satisfactorily treated by ordinary splints, or, as some surgeons claim, by no splints at all, I do not use these cases as evidence in favor of the method here spoken of.

The plan, as carried out in the first case, was certainly highly satisfactory, and I see no reason why it should not be of use in certain fractures in other parts of the body, where the fragments cannot be kept in position by the ordinary methods now in use. Dr. T. A. Deblois tells me that a modification of this method has been occasionally used in treating fractures of the nose; but at the time the cases here reported were treated, I was not aware of its ever having been previously used in any case.

One of the attractive features of this method of applying pressure is that the fracture can be reduced after the bandage has been applied, and the fingers and thumbs can thus regulate the degree and distribution of the pressure to a nicety.

It seems to me that Messrs. Wynne and Duel have suggested a new and simple expedient which may occasionally be found of great use in the treatment of certain troublesome fractures after the ordinary means have failed.

Clinical Department.

CASES OF PNEUMOTHORAX.[1]

BY H. F. VICKERY, M.D.

ON May 24, 1892, I was called to see Miss D. L., a rather delicate girl of nineteen, who had suddenly become very ill. As to the family history of the patient, her mother was robust; her father was not vigorous, but yet not suffering from any particular chronic disease; one sister had died of diphtheria, and an aunt of consumption.

Twelve days before I saw her, my patient noticed that she had to clear her throat oftener than usual; but she had no cough. Ten days later — two days before my visit — she had a slight hæmoptysis, followed in a few hours by a profuse one. She was apparently recovering from this as rapidly as could be expected, when in the night of the 23d–24th, she became suddenly cyanosed, and greatly distressed for breath. When I arrived, the heart was feeble and rapid, and demanded active stimulation. The chest presented the following condition: The left lung was normal, except for excessive, vicarious action. The heart was not displaced. The base of the right lung in front was tympanitic, and over it very little respiratory murmur was to be heard; but the heart-sounds were unusually audible in this region. The patient was too feeble to allow of examining the back. Dr. E. N. Whittier now saw the case in consultation with me. He also was struck by the remarkable transmission of the heart-sounds to the right, without any evidence of a consolidated lung. Nevertheless he concurred in a probable diagnosis of right pneumothorax, and he joined me in urging the removal of the patient to the Massachusetts General Hospital.

Accordingly, she was transferred thither, and entered Dr. Whittier's wards; where he very kindly invited me to see the girl with him, once more, in the afternoon of the same day. Hoping to relieve the dyspnœa, we inserted an aspirating needle in the lower part of the right chest. It entered a cavity, in which it could be freely moved about, and it is probable that we drew some air out of the thorax; but no fluid was obtained, nor was the patient rendered any less uncomfortable.

She did, however, benefit greatly by inhaling the oxygen which was ordered for her immediately upon her entrance to the hospital. It was given more or less continuously for the first twenty-four hours, and I think no one around her bed could doubt that it saved her life, at least for the time being.

After considerable improvement, however, fresh hæmorrhages occurred, the cough increased, tubercle bacilli were found in the expectoration, and on August 13th, after three months' illness, she died of pulmonary tuberculosis.

Around this case I should like to group a few others, some of which I have had the privilege of observing, but none of which have been under my own care. With one or two exceptions, to be hereafter noted, they have all been in charge of the Visiting Staff of the Massachusetts General Hospital, to whose courtesy I am indebted for permission to report them. It should be premised that it is not my endeavor to write a monograph upon the subject of pneumothorax, but merely to bring out a few interesting points.

One striking fact about the case just narrated was the abrupt onset of the trouble. The patient had had no real cough and only for ten days a slight hacking, when the hæmoptysis occurred, to be followed within forty-eight hours by the pneumothorax. A still more remarkable event is recorded by Lundie in the *Edinburgh Medical Journal*.[2] A lawyer's clerk, aged twenty, with a tubercular family history, but in apparent health, while sitting quietly at home after dinner, was seized with sudden severe pain in the left chest, and obliged to take to his bed at once, with left pneumothorax.

As regards etiology, my patient is an example of nine-tenths of all cases. Tubercular infiltrations, breaking down, open a communication between the bronchi and the pleural cavity. The tubercular focus need not necessarily be on the surface of the lung, however, for it may be connected with the pleural space by a sinus.[3]

The next most common cause is empyema, ulcerating into the lung. This was probably the mode of origin of a case of Dr. Gannett's: Case 2, Elizabeth S., whose father died of probable phthisis, had influenza in January, 1890, followed by pneumonia; after which it was said there was fluid in her chest. In May, she became much worse and had profuse expectoration, raised suddenly by mouthfuls. She was brought to the hospital June 7th, when the left chest

[3] Powell, quoted by Donaldson, Pepper, iii, p. 575.

presented the characteristic signs of amphoric breathing and metallic tinkling.

That violent exertion is often the immediate cause of pneumothorax is, it seems to me, illustrated by the fact that four times as many men as women suffer from it. In the first case reported in this paper, its development may have been precipitated by the coughing occasioned by the hæmoptysis, or by violent vomiting, which repeatedly occurred after the blood appeared. Strümpell has seen it after hard rowing, and after hanging out clothes. Child-birth sometimes causes it. A phthisical patient who was in Dr. Gannett's wards last October, was attacked while laughing. A painter (Case 3) also tuberculous, aged thirty-four, who was under the care of Dr. S. L. Abbot in April, 1882, when I was a house-pupil, was carrying either a ladder or a sign-board, when he experienced the peculiar sudden pain and dyspnœa.

Another man, (Case 4), Fred P., aged twenty-two, who worked in a stable, and who came under Dr. Whittier's care, had been well till one month before he entered the hospital, when he began to have a slight cough, with scanty, yellowish-white expectoration. These symptoms had lasted three weeks when, as he was engaged in washing carriages, left pneumothorax developed.

His case, by the way, illustrated the capacity of the thoracic cavity, which a valvular pneumothorax is calculated to test very thoroughly. Upon his being tapped with a trocar and canula, to which a rubber tube was fastened, with its other extremity under water, a considerable volume of air rushed out, and also sixty ounces of serum. Eighteen days later, seventy-six ounces were removed.

In Dr. Abbot's case, also, the distention became enormous, driving the heart under the right nipple, and urgently demanded interference. It did not get it, because the patient's friends forbade any "operation" — so that a sudden syncope ended the poor fellow's sufferings.

While in the vast majority of cases, pneumothorax ensuing upon over-strain is really due to an antecedent pathological condition,[4] it exceptionally occurs in those who were perfectly healthy before and who make a good recovery. This was true in both of Strümpell's cases, already referred to.

Another cause of the condition is traumatism. A perforating wound of the thorax may produce it; but it is much more likely to do so if the lung itself is pierced.[5] It must have been in this way that the two cases quoted by Osler [6] were caused by a hypodermic needle. Thus also contusions, without external wounds, may occasion pneumothorax; or old pleural adhesions, being wrenched asunder, may tear into the pulmonary parenchyma, as shown by Professor Zahn of Geneva.[7]

Often these traumatic cases do well.

Matt H. (Case 5), aged twenty-two, born in Finland, came into Dr. Fitz's wards June 27, 1891. Two weeks before, a knife-blade had been thrust into the upper right front. There were tympany, absence of respiration, and depression of the upper limit of hepatic dulness, with displacement of the heart to the left. There was no interstitial emphysema. He was discharged, well, at the end of two months.

[7] Schmidt's Jahrb., August, 1891.

Michael V. (Case 6), a Dane who could speak no English, entered the hospital May 27, 1891, with a small bruise low down in the right axillary region. There was much air in the subcutaneous tissues; and there seemed to be air and a small amount of fluid in the right chest. He was discharged, well, in fifteen days after entrance. At no time could any fracture of the ribs be made out.

As a rule, no abnormal condition causes so great a displacement of the heart as pneumothorax. Yet in neither Case 1 nor Case 2 was the heart dislocated. The same is true of Case 7, Annie G., sent in by Drs. Fifield and Fitz, and under the care of Dr. Whittier. When seven months pregnant, she had pneumonia, miscarried, and was delirious for five weeks. She entered complaining of cough with expectoration, and tenderness in the left axilla. The heart was in its normal place. No metallic tinkling nor succussion sound could be obtained, but tympanitic resonance extended everywhere below the fifth rib in the left axilla and the same level in the back, with very feeble, distant respiratory murmur. Over this same area it was noted that the heart-sounds were universally audible. This patient was discharged a month after coming in, improved, and wrote, twelve days later, that she was "gaining fast," and able to do a little work.

For the heart's remaining stationary, an easy and natural explanation is that pericardial adhesions have already been formed, in these cases, before the pneumothorax occurs. In Lundie's case, above-mentioned, the heart was pushed backwards.

Why heart-sounds should be occasionally transmitted through spaces filled with air, as in cases 1 and 7, is not very clear. It might be attributed to conduction along the ribs; but if so, it does not require any great intra-thoracic pressure, for there was evidence of none in the first patient. Possibly the concave thorax, with the air beneath it, acts as a sounding-board.

With regard to the detection of pneumothorax, I have been much impressed by the latency of some cases, and the comparative comfort some individuals enjoy, while the victims of this serious disorder. If only one's suspicions are aroused, however, it is seldom difficult to make a diagnosis.

Cornelius D. (Case 8), a hod-carrier, twenty-eight years old, entered the hospital May 28, 1887. He was a patient of Dr. Shattuck. For a year he had had a cough, and some pain in the lower part of the left chest, but he had worked till two weeks before entrance, when a sudden aggravation of the pain drove him to bed. He had noticed a swashing sound in his chest for six weeks before he took to his bed — that is, he had been working as a hod-carrier for six weeks while suffering from hydro-pneumothorax. On one occasion, by the way, just after this patient had been tapped, a bubbling sound could be heard at the end of inspiration, between the lower angle of the scapula and the vertebral column, suggesting that the hole in his lung was situated, not at the apex, as usually happens, but low down.

The most remarkable instance of latency in this disease, of which I am aware, is familiar to a great many, for it is related in Flint's "Practice of Medicine" (Ed. 1881, p. 154). An accountant, eighteen years old, had had a slight cough for a year, but so slight that he had thought nothing of it, and regarded

himself as being well, when he was taken ill with acute pneumonia, and was found to present, in addition, the signs of hydro-pneumothorax. He lived four days. An autopsy entirely confirmed the diagnosis and it revealed, beside, several phthisical cavities in the apex opposite the pneumothorax.

In the matter of prognosis, the phthisical cases are very apt to die in a month or two, but still they need not abandon all hope. Fräntzel has lately emphasized this point.[8] It is also illustrated by a case of Dr. Cutler's (Case 9). Patrick S., age twenty-three, entered the hospital July 23d of this year. He had had a "kind of a cough" for six months, and had lost sixty pounds. There was pneumothorax on the left side, and tubercle bacilli were present in the sputum. Yet, at the end of a month, he had gained seven and a half pounds, could climb stairs very well without much dyspnœa, and left the hospital "much improved."

The value of tubercle bacilli as a factor in prognosis is self evident; but a negative result of a search for them will not, of course, enable us to exclude tuberculosis. Thus (Case 10) Wm. H., who came under Dr. Shattuck's care March 9, 1891, with pneumothorax, had his sputa examined twice for bacilli, and none were found; while at the fatal termination of his disease the autopsy revealed a cavity in the upper lobe on the affected side.

As to treatment, for the most part it is symptomatic. Morphine is often necessary. And oxygen may be invaluable. Aspiration must be employed with some discretion. We can not afford to delay when the intra-thoracic pressure threatens to paralyze the heart, and on the other hand we must beware lest too zealous efforts cause a re-opening of a newly-healed communication between the bronchi and the pleural cavity.

Reports of Societies.

MASSACHUSETTS MEDICAL SOCIETY. SECTION IN SURGERY.

C. L. SCUDDER, M.D., SECRETARY.

MEETING, Tuesday, June 13, 1892, DR. C. B. PORTER in the chair.

DR. A. G. GERSTER, of New York City, read a paper on

HOW SHOULD THE GENERAL PRACTITIONER DEAL WITH STRANGULATED HERNIA?[1]

DR. C. C. ODLIN, of Melrose: It has always seemed to me that he who participates in a public discussion, even if he be devoid of the necessary oratorical accessories to hold the attention of his audience, should at least have a thorough knowledge of the subject under consideration. This I must at once disclaim. It has seemed to me perhaps that the only reason why Dr. Porter asked me to take part in this discussion was that the words of wisdom which we have heard might shine more brilliantly in comparison with my ignorance; but if that be the case I shall endeavor to forgive the doctor, and try to make some remarks on the interesting paper which we have heard from Dr. Gerster upon how strangulated hernia should be treated by the general practitioner from the standpoint of a general practitioner. I remember very well, indeed, with what a sinking of the heart I was in the habit in my early days of responding to a call to see a person afflicted with irreducible hernia. I revolved in my mind the different coverings of the hernia — integument, intercolumnar fascia, fascia propria, etc.,— and by the time I got to the house those were a muddle in my brain. That was all nonsense: I know now it was, but I didn't know it then. Had I known it then, I should have been saved a good deal of mental anxiety and worry. It seems to me that when the general practitioner is called to a case of hernia he should go to that case with just two ideas in his mind, one is to reduce the hernia without operation if possible, the other is to reduce that hernia any way. Of course, we all understand that taxis is the first thing to attempt. Taxis, it seems to me, should not be prolonged, and should not be severe lest the subsequent bruising may interfere with the recovery of the patient if operation be finally necessary. Taxis may be assisted very much by the use of ether and the ether spray; and it seems to me also by placing the patient in the Trendelenburg position. If my memory serves me aright, this was first attempted by Dr. William J. Allen, a practitioner at White River Junction, Vt. He mounted the bed, lifted the hips and body, and allowed the head and shoulders to rest on the bed. The gut returned with that gurgle which is so pleasant for the practitioner to hear.

If taxis is unsuccessful, of course the question of operation at once comes up. I want to speak of three points which have occurred to me in the cases upon which I have operated. One is the point Dr. Gerster has spoken of: to be sure of the diagnosis. Quite a number of years ago a gentleman who was a patient of mine a long time, came into my office and showed me a very small bunch about the size of a pea in the left groin. I examined that as carefully as I could, and told him I was unable to determine whether it was the commencement of a hernia or whether it was an inguinal gland. As this gentleman was going into the city every day, I asked him to call upon a surgeon who made the subject of hernia a specialty. A few days afterwards he came to my office and said he had visited the gentleman, and had been told it was an enlarged gland and that no truss was necessary. Nearly a year later, while getting out of his buggy, this little bunch broke through, forming a protusion about the size of a hen's egg. I was summoned immediately, and found it impossible to reduce it. As I was called in the late evening, I packed the tumor in ice, thinking the cold, perhaps, would enable me to reduce it when morning came. As it was impossible to do so, I operated the next morning. There was no difficulty at all in returning the hernia; but the gentleman sank and died, apparently of exhaustion. That is a case in which I have felt, had I been acute enough to have distinguished that hernia in its commencement, a human life might have been saved.

Another point I wish to touch on may be spoken of perhaps in connection with another case. I was asked to see a woman about thirty years old afflicted with strangulated hernia. I advised immediate operation, and operated. The bowel moved freely after the operation, but the woman commenced to vomit; and she died, I think, on the fourth day. It seems to me, in the light of later experience, that the proper thing to do in a case like that is to perform laparotomy, feeling

[1] See page 61 of the Journal.

[8] Schmidt's Jahrb., December, 1891.

that there might be some obstruction farther up the intestine.

The last point that I will speak of is that I do not think any one should hesitate to operate, no matter how unfavorable the conditions may seem to be. Some time ago, one hot day in July, I was asked to see an old woman of Irish extraction, about seventy years of age as near as I could tell. I found her in a hovel of two rooms, surrounded by pig-pens; hens were kept in the back part of the house. The room in which she lay was infested by hen lice. She had been vomiting four days at the time I saw her. I found a hernia about the size of the two fists. It seemed, certainly, as if no operation could benefit that woman; but I thought it my duty to give her what chance there might be. I endeavored to render her as aseptic as possible, etherized and operated. On getting down to the constriction, I found, in order to return this enormous mass, I had to cut to such an extent when the bowel was returned and the finger was removed, that the whole contents apparently of the abdomen poured out again. I never had such a condition before, and hardly knew how to proceed. I took a needle and silk, and sewed up the constriction, getting tissue from the internal iliacus muscle in which to catch my needle. The old lady was out in about a fortnight feeding her pigs; and since that experience I have felt that there are no conditions, no surroundings so bad that any physician should hesitate to give any patient the benefit of an operation.

It has seemed to me that there is no class of cases in which we have our surgical landmarks so clearly defined as in hernia; and I believe that any general practitioner with a cool head, fairly steady hand accustomed to the use of the surgical knife, and a clear conscience should not hesitate to operate upon a case of strangulated hernia, and that it would be criminal to allow a patient to die because a professional surgeon was not within reach.

Dr. William Bass, of Lowell: I appreciate very much the paper we have heard to-day, and there is not much left for me to say. The ground has been very well covered. In that paper it seems we have a right to infer that we are all experts in the matter of surgery and in operating on strangulated hernia, which unfortunately is not the case. I will admit that our school educates every young man in a manner that he should be competent to deal with strangulated hernia; but there are some of us a little timid, and we are not all located near the city or near some expert man in the matter of surgery, and we might have to rely, in some back town or some wood-chopper's camp, upon ourselves. Now what will such a man do? Of course, when he undertakes the practice of medicine and surgery, he assumes that he is competent to attend to the business. Now then, of course, he understands the anatomy of the case and has seen the operation done; but he never was called upon to do it himself. This is his first opportunity; and what shall he do? Perhaps he may be by candle-light in a hut. He has got a difficult task for himself; but there is only one thing for him to do. He cannot retreat. He must operate if he cannot reduce it with taxis and under the influence of ether; consequently he makes the best of it. If he has nothing but a pocket-case, he proceeds with that; and in these times he must make his patient as near aseptic as possible and himself and the surroundings, which might be a difficult matter to do. Well, of course, he must operate under the circumstances; and if he is of the character of a man I met the other day, he will do very well. I will mention the case, though it is a little off from the subject. I was notified that I was wanted to bring my tracheotomy tube, and I hurried as much as I thought necessary; and when I got there I found the young doctor in attendance had already operated. As luck would have it he had left his pocket-case at home. Some man about the house had a pocket-knife, and that was dull. They sharpened it; and the doctor took the pocket-knife, and opened the trachea and found he had no tube. They found a piece of rubber tubing, and that he inserted. Now then, if our country doctor is of that character, he will get along very well; and, of course, a general practitioner must of necessity, if he is going to make a success, be an all-around man, be a man prepared for emergencies. A specialist, if he is not a very smart man, can make a good practitioner of himself in some specialty. He has not so much ground to go over; but a general practitioner needs to be an extra smart man. As I said, I had not much to say; I wanted to help out this man in the backwoods a little. Now then, after he has operated, if he finds the gut gangrenous, about the best he can do is to make an artificial anus; and at some future time some man of more skill, or with assistance, can resect and remove the portions of the gut that are gangrenous and bring the intestine together and make a whole alimentary canal again.

Dr. H. H. A. Beach, of Boston: I have listened to Dr. Gerster's paper with the greatest possible interest. In twenty-six years' work in private and consultation practice and in hospital service I have seen most of the emergencies, most of the conditions that Dr. Gerster has spoken of. One great thing that has impressed itself upon me is the importance of an early diagnosis, an avoidance of excessive taxis — just the two main points Dr. Gerster has laid most stress upon; and I should hope he would have the thanks of the Society for laying aside the traditions of obsolete surgical work and really bringing the technique of the operation for herniotomy up to the standard of modern abdominal surgery. The essential points, are early diagnosis, avoidance of excessive taxis and prompt operation, restoration of the gut to the abdominal cavity without pulling and hauling, which can only be done by free and adequate surgical incisions, and the most complete antisepsis that is possible. It seems to me he puts the operation right on a line with the prompt and adequate treatment which can be applied to extra-uterine pregnancy and to appendicitis. Prompt action is the only thing that insures success. The disasters of the three diseases may be nine times out of ten attributed to delay in diagnosis, delay in operation, insufficient antisepsis and overthumbing, manipulation of the parts.

For one, I desire to express my warmest thanks to Dr. Gerster for his very interesting paper and the way he has put it before the Society for the general practitioner.

Dr. John Homans, of Boston: I am sorry to say I did not hear Dr. Gerster's paper, so that I cannot speak of the points he made. The subject, as I read it, was how should the general practitioner deal with strangulated hernia. I suppose the general practitioner in a case of strangulated hernia has got to act according to his ability. He must, if he is capable of

doing it, operate and return the intestine if it is, in good condition, and try to cure the hernia at the same time. It seems to me that a general practitioner in a city could perfectly well avoid the case by sending the patient to the hospital or sending for a surgeon. In the country, where a man is more on his own resources and develops more in the operations than a man does in the city, he has got to face the music; and if he has a gangrenous bowel, he must excise it if he can do it. The general practitioner in the country is especially skilful, it has always seemed to me, in the treatment of fractures. He gets very good results. I do not know whether this paper goes into the general treatment of hernia. Certain cardinal points about the treatment of hernia are almost self-evident to one who has had experience. We get cases in the hospital after some one has squeezed them so that they are gangrenous both by delay and contusion. Indeed, I have seen a hospital surgeon squeeze a hernia with great force, and he has asked me to put my hands outside of his and squeeze; but the result was fatal. You have got to have a general practitioner, a good one and of some intelligence, to treat these cases; and if in the country he must meet all the emergencies, if in the city he can avoid them. I have no doubt the subject has been well described and the emergencies dealt with by Dr. Gerster, and I will not go into the general treatment of strangulated hernia. One of the most remarkable cases I know of strangulated umbilical hernia was one where Dr. Richardson removed some nine inches of the bowel, sewed the ends together, and the woman I think had a movement of the bowel within ten hours. You cannot expect every general practitioner to make an excision of the bowel with the skill of Dr. Richardson or of Dr. Gerster; but he must be prepared to meet emergencies, and particularly to recognize the fact that he must not lose time by taxis, particularly forcible taxis at the risk of doing a great deal of harm.

DR. A. T. CABOT, of Boston: I was unfortunate in not hearing the first part of Dr. Gerster's paper in regard to taxis, and very probably he made a point I should wish to make — that one can be much more free with taxis in the very commencement of a hernia when it is new than later. In fact, I should almost say it was best to forego taxis altogether in a distinctly strangulated hernia, that had been down more than four or five days, in order to avoid the possibility of rupturing the very much weakened gut by the taxis. I had a case that illustrates how easily one of these guts can be ruptured. It was in a patient who came to the hospital with a hernia that was quite reducible, but with difficulty. He had had it a great many years and was in the habit of reducing it. This time it had been down a little longer and went back hard. Just afterward he was seized with violent pain, and brought to the hospital twenty-four hours later. I did immediate laparotomy, but the patient was almost moribund when we began, and lived only a few hours. The condition was a minute rupture the patient had made on his own gut in reducing it.

I was very much interested in what Dr. Gerster pointed out as a necessity for great caution in opening up the neck of the sac in cases which have been strangulated some little time, in which there is a strong possibility that the neck of the sac has been so nipped that there is a weakened line around the neck of the hernia where the gut is ready to give way. It is in those little herniæ, particularly at the femoral ring, where the danger is greatest. In large herniæ there is less danger of cutting at the constricting point than in the small herniæ. The gush of fæcal matter I have seen once or twice when the neck of the sac was divided. It is immediate and difficult to handle unless you have a large enough opening already to allow of the free escape of the fæces outwards.

It seems to me his recommendation that in all these cases the division should be from without inward is very pertinent, and it is one I shall put in practice more than I have hitherto done. I had a case a fortnight ago. The result was unfortunate. The hernia had been strangulated eight days and the gut was gangrenous. In that case, I opened up the neck in the way he describes, making really a laparotomy, cutting down above the neck of the sac and incising through the neck rapidly and pulling the gut outside at once. I secured it out by drawing a strand of iodoform gauze through the mesentery to hold it back, and surrounded that iodoform gauze in the manner he describes, but the patient lived only two days. She was an old woman and very much exhausted. I think the point he makes is a very good one and I shall certainly be encouraged by his precept to follow it up more fully, coming down on the neck of the sac with the eyes upon it, so that if there is a little line of gangrene you can at once see it and treat it with consideration.

DR. C. B. PORTER, of Boston: I don't think it is customary for the chairman to make remarks upon the subject of the paper, but there are one or two things I should like to speak of. Dr. Gerster considers the question of the action of the general practitioner, and lays great stress upon the highly antiseptic condition to which the patient and the operator should be brought, and it seems to me if I can say just one word in regard to what a country practitioner did in a case I afterwards saw, it would help perhaps some one placed in the same unfortunate circumstances. A patient met with a railroad injury, which produced a compound and comminuted fracture of the patella. He was at a distance from a surgeon, but he was under the care of a good common-sense man, who understood details if he could not carry them out. He had no antiseptics by which he could render anything sterile, but he had boiled water and soap, and he rendered the parts thoroughly aseptic by scrubbing with boiled water and soap and scrubbing his own hands, and he laid open the knee-joint as for incision, put the flap back into place, and sent the patient to the hospital with the wound practically healed. He had none of the necessary things about him to do this operation, but he did it practically aseptically by getting his own hands clean, the field of operation clean, and operating under these circumstances. I certainly was impressed in connection with the paper with regard to the stress laid upon early operation and upon the use of slight taxis. I do not want to say anything further on that myself. It seems to me that there is where the general practitioner fails more often in dealing with this subject than in any other, in the first place, in not recognizing the fact that a strangulation which will not take care of itself must have assistance; therefore the sooner it has it the better. I think it has been very aptly compared by Dr. Beach to appendicitis and to extra-uterine pregnancy.

DR. GERSTER, of New York: I shall have very few things to add to what was said by myself and the gen-

tlemen here who were kind enough to join in the discussion, and I see only one thing noted down that I believe is worth while bringing up once more, and that is the remark made by Dr. Odlin. He said, if I understood rightly, if he had done a herniotomy and the patient continued to vomit that he would not hesitate to do a second laparotomy. I believe that that is a suggestion worthy of attention, and a suggestion along the lines of which surgeons have already tried to walk; but let me tell you that they have not always been successful. I have seen a number of cases where the intestine was found to be in a normal condition, where it was reduced, where no complication arose during the course of the operation, where we expected immediate relief from the vomiting. It is a charming thing to see, in a man who was vomiting every two or three minutes, the moment the constricting band is divided all these disagreeable and distressing symptoms cease. Now when we see that this is not the case, there is grave trouble present; and I am sorry to say it is very frequently a trouble which is not within the pale of a surgeon's help. It is very distressing after we have performed a good operation and made a favorable prognosis, which is the most disagreeable part of the whole thing, to see the patient go on vomiting as if no operation had been performed, and ultimately go from bad to worse and die; and it is worth our while to know why that is the case.

Do not let us misunderstand each other. I do not mean cases in which the surgeon performed the herniotomy correctly as far as the technique of the operation is concerned, where the strangulation was relieved, the bowel replaced, where the surgeon has infected the wound and caused a septic peritonitis. I mean something quite different, and to explain to you what I mean I shall illustrate by a case which I am sorry to say occurred to me only recently, and the memory of it is imbedded in my mind in deep letters. The hernia had been strangulated a long time and there is the essential part, the longer the strangulation has existed the more probable this occurrence, and it illustrates the serious effects of long-continued strangulation — not only upon the strangulated gut, not only upon that part of the strangulated gut which is actually constricted, but upon the entire intestinal tract and upon the entire system of the patient. You may find a case of that kind and the gut not gangrenous, the obstruction in the gut due (as was in this case) to the presence of a square piece of potato which was within that portion of the gut which had left the abdominal cavity and by its mechanical presence obstructed the flow of the intestinal contents. The walls of the gut were normal, slightly congested, but no signs of gangrene; and I believe gangrene would never have come in that case. He died, not from strangulation but something else. The hernia was cut down upon, that hard body was found in the knuckle of gut, crushed between the fingers, put out of the way, and the moment that was done the gut slipped back so that I had to catch it in order to have a chance to examine it. I withdrew the gut without difficulty, showing there was no real strangulation. It was an obstruction by flexion caused by this foreign body. I mean by flexion that condition you observe in a rubber-tube which you bend. You see a knuckle forms and no amount of pressure will force liquid through that bent portion of the rubber-tube. Just as the rubber-tube is bent and occluded so the intestine is bent and occluded and the symptoms are practically those of obstruction. The intestine was examined, found to be normal and reduced. I withdrew from the family giving a favorable prognosis; and I was very much set back when I came the next morning and heard the patient had been continually vomiting fæcal matter as before the operation. The obstruction had lasted five days. I said to myself, in the presence of these facts, knowing that I had reduced the trouble within the hernia, there must be some cause of obstruction higher up than the hernia was situated. The hernia contained a part of the small intestine, what part I could not say then. Seeing the patient continually vomiting matter that was feculent, liquid material, I at once suggested that we open the abdominal cavity, expose that portion of the gut which was just above the inguinal region, if possible hunt up the knuckle that was contained in the hernia and then try to find the cause of this obstructive condition. This was agreed to, and the hernial aperture was reopened, incision extended, and I satisfied myself that there was no portion of the intestine that had again entered into the wound. No radical operation was performed, and the contiguous portion of the intestine was easily found and exposed. I failed to find any signs of constriction; but I noticed that although there was no constriction present, that portion of the small intestine leading away from the knuckle that occupied the hernia was shrunken up and empty, whereas that portion leading to the knuckle from above was distended enormously, contained a large quantity of gas and liquid fæces. The walls of the intestine were very much thickened, œdematous, the mesentery was congested, (intensely so), as was the entire intestine; and although I could not find any constriction, I saw how far the trouble extended down to the knuckle contained in the hernia. Now there were all the symptoms of obstruction of the intestine and no cause for it whatever. I enlarged my incision, and brought out more of the intestine; as far as I could follow, I found this identical state. I said, "I never have seen anything of this kind"; replaced the intestine; closed the wound; and fell back upon symptomatic treatment in the good old-fashioned way, which resulted in the good old-fashioned way — in the death of the patient.

Post-mortem, we found that in this case the only cause of the persistent vomiting of the patient and of his ultimate exhaustion and death was nothing but an intense congestion or rather a paralysis of the afferent or proximal portion of the small intestine due to the intense congestion which was started and to the prolonged retention or stenosis of the contents of the gut. In addition to that there were reasons to assume that there was also sepsis present, not due to the herniotomy, but rather to exosmosis of the intestinal contents, that is passing through the congested and abnormal intestinal walls of infectious material into the peritoneal cavity. It has been established by experiment on animals, that when the intestine becomes congested and inflamed, not only paralysis of its muscular coat and enormous distention of the intestine and inability to propel its contents result, but that the infectious bacilli contained within the intestine, within the fæces, will find their way out through the intestinal walls into the peritoneal cavity and produce an intense peritonitis; and I believe that in this unfortunate case we have seen a counterpart of the experiment which has been performed repeatedly on the animal. I believe this man died in consequence, first, of paralysis of the

afferent or proximal portion of the small intestine, of exosmotic peritonitis, although we did not find sufficient reason to make the diagnosis of peritonitis as we used to make it ten or fifteen years ago, when we believed it could be diagnosticated only where the intestinal coils were agglutinated, etc. Nowadays we see patients die, after a laparotomy, with all the symptoms of peritonitis, and we find post-mortem a slight serous exudation, sometimes not even turbid, and a very moderate amount of hyperæmia of the peritoneum. Many of these cases have been in the early days of laparotomy classed under the name of shock, and wrongfully. Nowadays we know these cases are septic peritonitis.

DR. CABOT: In regard to the treatment by the general practitioner where he has sent for the surgeon, I would say that it has occurred to me to be called several times to such cases, in which I should have been very thankful if the general practitioner had prepared the field of operation for the surgeon. I think it would have been a very great assistance; and if general practitioners who do not intend to operate and have sent for surgeons would always apply an antiseptic packing over the field of operation, anticipating the surgeon's arrival, I think it would help the result very much.

SUFFOLK DISTRICT MEDICAL SOCIETY.

JAMES J. MINOT, M.D., SECRETARY.

ANNUAL meeting, Saturday, April 29, 1893, DR. E. N. WHITTIER, President, in the chair.

DR. H. F. VICKERY read a paper on

CASES OF PNEUMOTHORAX.[1]

DR. A. L. MASON: I should like to ask the reader if, in cases of pneumothorax, he would not expect usually to find pus in the cavity as well.

DR. VICKERY: Yes sir; I should say that was true in a large number of cases, but it is not a rule, without exception. I did not mean to imply anything about that in the paper.

DR. MASON: I ask because the question often arises as to the propriety of a permanent opening and drainage; as to whether these phthisical patients may be benefited by removing the pressure of the air and fluid by permanent drainage. As a rule, it is not advisable. I have in mind a number of cases in which the patients have insisted on something radical being done and in which life was prolonged perhaps by drainage and subsequent occasional washings. If the pulmonary fistula cannot close, there is no chance for lung expansion and such cases are not suitable for resection of ribs. When the pneumothorax is circumscribed as a result of pulmonary abscess or of empyema with perforation of the bronchi, drainage is absolutely necessary. Two or three such cases I have observed at the hospital with permanent cure, those cases being probably non-tubercular. I think that one of the cases that Dr. Vickery mentioned was of that kind.

DR. ELLIOT read a paper on

HYSTERECTOMY FOR FIBROIDS, WITH CASES.[2]

DR. HOMANS: I will try to avoid the narration of cases and to talk about the general subject. In the first place, in regard to the frequency of fibroids. In the last fifteen years I have seen six hundred cases of fibroids. I have operated on about sixty-five of these. That seems a small percentage, and very likely I ought to have operated on as many more, but some of these patients come once and I am in doubt whether to operate and I never see them again. In the last six weeks I have operated on nine cases. Now if one man has seen six hundred cases in fifteen years, it is rather a frequent disease. Sometimes these tumors, if not very large, disappear after pregnancy. I have seen such a case in the wife of a friend of mine. The woman became pregnant, aborted at about the sixth month and the tumor entirely disappeared.

The question of diagnosis is important. I saw a lady who was sent to me by a distinguished accoucheur with the diagnosis of fibroid to be removed. I examined her carefully and said I thought she was pregnant, which proved to be the case, and she was delivered at full term. The diagnosis, of course, is very important in these cases.

In regard to the size of these tumors. Sometimes the small ones cause as much trouble as the big ones. I have removed a small tumor not bigger than a horse-chestnut, because the lady could not sit down. She felt, as she said, as if she was sitting on a spool all the time. I opened the abdomen, removed the tumor from the posterior face of the uterus and she did perfectly well, and was entirely relieved.

Another cause for removal is hæmorrhage, another is pain and another the position of the growth. The reason I removed the tumor which I now pass around was on account of pain. The woman was about thirty years of age, and her life had been one of suffering for about six years. In operating I had to enucleate the tumor and treat the stump intraperitoneally. The operation took two hours and everything was removed except the button of the uterus just inside the vaginal septum. I could not drag up the tumor so as to put the wire under it. Both ovaries had a brownish-looking fluid in them which I thought might be dermoid, but they have not been examined as yet.

In regard to the treatment of these tumors. Having operated a good deal up to 1888, I got a letter from Dr. Keith, of Edinburgh, saying I must lay down my knife for fibroids, and that Apostoli's method would cure them. I got Apostoli's book and for eighteen months I worked at this tiresome and tedious process. It almost always stops the hæmorrhage, particularly if it is used at or near the menopause, the two causes combined, the electricity and the menopause, are very apt to cause a cessation of bleeding and sometimes a diminution in the tumor. I have never seen but one tumor disappear and it was in a woman who had only two treatments. How much the treatment had to do with it I don't know, but two years later the tumor had entirely disappeared. The Apostoli treatment will relieve pain in a good many cases. In a certain number of cases it will apparently arrest the growth, but it is unreliable.

Dr. Elliot spoke of the tendency of these tumors to become malignant. Whether they become malignant or the uterus becomes malignant, I don't know, because I have had no autopsies. I have operated on a lady over seventy, for a large ovarian tumor and at the operation have found a fibroid entirely calcareous. I did not meddle with it. Three years afterwards she developed hæmorrhage and now has cancer of the uterus. I have seen that same thing occur in, I think, two other cases.

[1] See page 64 of the Journal.
[2] See page 57 of the Journal.

Sometimes, as you know, these tumors are enucleated by nature through the vagina. I remember a case where I removed the ovaries for the cure of the fibroid. The woman had excessive hæmorrhage and I removed both ovaries and tubes. The hæmorrhage continued. At the end of two years she came again and the tumor was protruding through the os uteri and I removed it. Nature had cured her and she had lost her ovaries unnecessarily. I saw another lady whose husband asked me to have Dr. Keith come over from Scotland to see her. He came and advised against an operation. Within two years the tumor was extruded and was removed through the vagina. If you could tell whether these tumors were going to grow, or remain quiescent, or to be extruded, of course you would know when to operate and when not. Each case has to be determined on its own merits, and there ought not to be any rule that all uterine fibroids should be removed or should not be removed. Treatment by removal of the ovaries I think has been very much abandoned. Another lady I operated on for a fibroid successfully by the extraperitoneal method, and she subsequently developed cancer in the neighborhood of the scar and stump.

Dr. Elliot has spoken of the Trendelenburg position which is extremely useful. I could not have done anything without it in the removal of the tumor I have just shown you. The Trendelenburg position is one of the greatest advances of modern surgery. Some of my cases I have watched from five to thirteen years, and I intend to look up all my cases and see what has been the result in those who have had no treatment and in those who have been treated. Some of them I have watched and seen the tumors disappear of themselves. In some the tumor has not grown much larger and in some I have erred in not operating and they have been operated on by others. Some I have seen remain about the same. If there are no symptoms of hæmorrhage or excessive pain, frequent micturition or emaciation, I generally ask these people to come to see me once in six months and I am ready in that way to interfere if necessary. In some I have advised immediate operation.

The mortality of the operation is now much smaller than it used to be. I have operated on sixty-five cases with fourteen deaths. Forty-nine were treated extraperitoneally, sixteen intraperitoneally. The extraperitoneal had ten deaths and the intraperitoneal four. Now before 1887 I had done twenty-seven operations with seventeen recoveries and ten deaths, so that that makes my whole statistics, which of late years have been very good, much less good than it would have been if I had been able to operate better some years ago and had had better cases. The largest tumor I remember to have removed weighed fifty-two pounds. The patient recovered and has been well ever since.

The treatment by the intraperitoneal method has been very much improved of late years and can now be done in the majority of cases if the surgeon chooses to. The extraperitoneal treatment by the wire is quicker and saves a good deal of shock and a long operation, but the convalescence is long and tedious. What operation leaves the patient in the best condition as to future comfort is not yet determined.

For about a year and a half I treated all the patients who came to me by the Apostoli method, but it is a method requiring a person of an extremely calm, patient and sanguine temperament to practise it.

It is a very trying thing for the patient to have a severe cough after one of these operations. A week ago I operated on a woman at the hospital and found a hard mass in the umbilicus. The umbilicus is a frequent seat of cancer, so in doing the operation I cut out the umbilicus with its contained growth, on which I have not yet had a report. Two nights ago the woman had a severe attack of coughing. This place gave way and the bowels and omentum protruded. They were put back and the wound sewed up. I am going to operate Monday on a woman on whom I operated a year ago and the woman has a hernia from the scar where the wire came off.

There is another reason for operating on these tumors, and that is, they sometimes become entirely separated from the uterus. I have seen them sometimes with a small pedicle, but they sometimes become *entirely* detached from the uterus and are nourished by their adhesions. Those tumors are dangerous and I have seen one of them produce fatal strangulated hernia, from the intestine passing through a gap between the adhesions where the vessels came from the intestine, so that a movable tumor of the abdomen which you cannot locate as connected with any viscera ought to be explored to see if it is a wandering fibroid.

With the extraperitoneal treatment I have lately adopted the following method of treating the stump. I have, at the end of ten days, given the patient a little chloroform and tightened up the wire, and if the wire does not break the stump is cut off and drops back. I think this is better than cutting it off with the scissors or knife which is sometimes followed by hæmorrhage.

I do not know that it is worth while to go into the symptoms and sensations that people feel who have lost their uterus and ovaries. They suffer from hot flashes, whatever that means. The sensation is as if a lot of hot blood rushed to the head. Some have it once a day and some every five minutes. It is very troublesome and trying. I suppose after a year or so it subsides. Most patients grow fat.

I would then say that if a patient suffers from excessive and severe pain, suffers from hæmorrhage, if the tumor is evidently growing, if the woman cannot stand the tumor on account of its looks, or if it embarrasses her, although she may have no pain or hæmorrhage, so that she cannot stoop down to lace her boots and cannot walk with ease, then I think the tumor should be removed. I think the woman has a right to have the tumor removed for the looks if she chooses to. Where there is any doubt in my mind I ask them to come again and I try to keep up correspondence with them, but I have almost entirely abandoned the Apostoli treatment and I think I operate now for the removal of these tumors oftener than I used to.

DR. MIXTER showed a fibroid he had recently removed and said: This tumor is very much smaller than when it was first removed, as it was one of the so-called juicy fibroids, very œdematous, the whole thing weighing about thirty pounds. It is very flabby and at the time of operation it was filled with fluid and perhaps as large as it is now. This patient had carried this tumor for eighteen years and about eleven years ago she consulted surgeons in Boston and New York who advised against removal. Since then it has grown slowly, she now is thirty-nine years old and she could hardly carry this tumor around. She could not turn over in bed without lifting the mass, she was very

much emaciated and had had two very severe hæmorrhages during the past year, which had almost proved fatal. The operation was an easy one comparatively. There were few adhesions. The stump was treated intraperitoneally. I had hoped that Dr. Elliot would say something about the treatment of the stump and it was on that subject that I wished to speak in connection with this tumor. I can only say that this stump was treated intraperitoneally in one way, that is, as much of the peritoneum as possible was sewn over the stump, the uterine arteries being tied, one of them outside of the ureter, the ureter being found first and then the uterine artery and veins tied and then a safety suture being passed through the stump it was dropped back and packed around with iodoform gauze, thus completely shutting it off from the general cavity of the peritoneum and any hæmorrhage taking place would come up from the lower end of the wound. Two stitches were left untied and so in case of hæmorrhage it is easy to pull up the stump. No hæmorrhage took place. The gauze was removed at the end of forty-eight hours and the remaining stitches tied. There has been no suppuration whatever and the patient is perfectly well, normal temperature and pulse, and I think will be sitting up within a few days. I have never seen any reason for keeping patients in bed after laparotomy any great length of time, unless there is some open wound. In this case I think ten days will be sufficient.

The tumor is interesting, as showing these large divisions and lobules, which could be easily felt through the abdominal wall. Here is one of the ovaries which is concealed by them. The other ovary was free. The whole of the uterus, with the exception of a very small button, was removed at the time. The length of the pedicle was interesting in this case, showing how a tumor, carried as long as this one, stretches out the pedicle sometimes and it looked not much larger than an ordinary ovarian pedicle. As you see this is not now a particularly large tumor.

The treatment of the pedicle is where one has to use, perhaps, more judgment than in any other part of the operation. There is no one method applicable to all cases and there are three or four which can be used with advantage under certain circumstances.

DR. CUSHING: I think that one of the greatest advances in the whole question of fibroids, has come up recently, in the improved intraperitoneal method of treatment of the stump. The previous treatment by Schrœder's method was by merely tying two flaps together by force of ligatures, which often were too tight and liable to cause sloughing, or too loose, and thus permitting loss of blood. The extraperitoneal treatment by the wire or rubber ligature was therefore usually preferred, except in Berlin; this is a rapid way of getting through the operation, but makes a long convalescence, and as it was formerly used, the pedicle being very large, was apt to cause a sloughing stump. Recently, however, there has been a great improvement in forming the pedicle, either with the wire or with the internal treatment. No matter whether the tumor is above or below the peritoneum, most of it can finally be reduced to a little pedicle. By tying the uterine arteries on the side, the bleeding can be entirely stopped. That idea I think was first introduced by Chrobate, who advised tying the uterine arteries on each side, dilating the cervix and pulling a wick of gauze through it from above downward and then closing the flaps of the pedicle together and matching the peritoneum over it. It makes a nice little stump like that of an ovarian tumor. The first three cases I did by Schrœder's method in 1887, died, then I treated extraperitoneally twenty-five cases with twenty per cent. of deaths. I lost two, the last of these cases, last summer, without any reason I could see except obstruction of the bowels. I concluded to use the intraperitoneal method just described. I have operated on twelve cases in this way. All recovered without trouble. The convalescence is shorter, the pain less, and the operation not very much longer. It is often important, I think, to use a temporary rubber ligature in forming the pedicle, as it is much easier to tie the uterine arteries after the pedicle is formed and the mass of the stump is removed, than it would be previously. I will not discuss the total removal of the cervix at this time; I have done it, but prefer the method described above.

I agree with what Dr. Homans has said in regard to the indications: the pain, the pressure, the hæmorrhage, the growth and even the desire of the patient to be rid of the tumor. If there is any one thing well settled in modern times it is that a fibroid tumor is not the innocent thing it was formerly supposed to be. A common impression in the minds of the profession as well as of the public, is that nine-tenths of these tumors will go away at the menopanse. Probably the ones I see are those which do not go away. I often see a woman with a tumor that begins to grow at the menopause. A fibroid tumor which has begun to grow at about the menopause is one of the most dangerous things a woman can have, and the sooner it is removed the better, in my judgment. With the modern methods of treating the stump, there is no more danger in removing a fibroid than in removing any ovarian tumor, and I think the whole trend of expert opinion is towards removing earlier, if the patient consents; not to wait until she is run down, until pressure of important organs occurs, but to remove the tumor early. I have three patients on whom I operated week before last, one for hæmorrhage, one with a tumor retroverted and bound down by adhesions and pressing on the rectum, and the third for pressure on the ureters and renal colic at times and symptoms which showed, if it went on much longer, it would be a very serious matter.

As for the Apostoli treatment I used that faithfully in several cases and I have had to operate on some of those same patients since. I have had the same experience as Dr. Homans and have given it up. To use this treatment properly and without danger, requires a very great amount of most delicate and careful antiseptic work. I have seen plenty of cases where patients have been made worse, abscesses have formed, infection of the tubes has been set up, which was reasonably attributable to the Apostoli treatment, or the attempt to use it. I think it is a form of treatment which does not belong to the active surgeon, but to the careful work of the office practitioner.

DR. HOMANS: In reference to what Dr. Mixter said in regard to keeping patients in bed after a laparotomy, I have a patient from whom I removed a fibroid about four weeks ago by means of the Mixter clamp. This woman has got up almost every night since the operation and wandered about and the night nurse has found her up and about with this thing dangling from the stump. It has not done her any harm.

Dr. Elliot: Dr. Homans mentioned a case to me either privately or to-night, where he took out the stitches on the eighth day and the patient coughed the intestines out. This shows it is not safe to let a patient up on the tenth day. I think there is danger of hernia in letting the patient up before three weeks after hysterectomy. I let them up in two weeks after a simple ovariotomy.

Dr. Mixter: It seems to me that under certain circumstances it is well to keep the patient in bed. If, however, the incision has been closed completely and apposition has been good with a tight swathe and suitable padding and the abdomen not distended by gas, there is very little more pressure with the patient in the erect position than in bed and moving around. I have never seen any harm from such a course. I do not believe in keeping patients in bed after any surgical operation longer than is absolutely necessary. In breast operations I think it is well to get them out of bed the second or third day. Their convalescence is much more rapid.

Dr. Elliot: The intra-abdominal pressure on the abdominal wound is immensely increased when the patient stands. There is the weight of the intestines and the pressure of breathing comes down and out. Some laparotomists have reported five per cent. or six per cent. of hernias. I am sure it is an everpresent danger and I think one cannot take too much care. So far as the menopause goes, my experience would agree with that of Dr. Cushing.

Dr. G. H. Monks showed

A METHOD FOR APPROXIMATING THE FRAGMENTS IN A CASE OF FRACTURE OF THE RADIUS AND KEEPING THEM IN POSITION,[3]

recently used at the City Hospital.

Recent Literature.

Public Health Problems. By J. F. J. Sykes, B.Sc., M.B. London and New York: Walter Scott and Chas. Scribner's Sons. 1892.

This compact but comprehensive book is one of the Contemporary Science Series edited by Havelock Ellis. The author is the medical officer of health of one of the populous London districts, and has brought together in this volume his views upon matters pertaining to public health in a philosophical as well as practical manner.

The author's line of argument is foreshadowed in the following extract from the introductory chapter:

"Public health in its later developments has realized that it could never hope to satisfy its aspirations by the prolongation of the existence of the more favored members of the community. Its greatest justification lies in increasing the health and power of the workers, and especially of the industrial classes, those less able to help themselves. It is distinctly socialistic in its tendencies, as distinguished from individualistic: it is, in the widest sense, humanitarian. . . . It is well-nigh impossible to form an adequate conception of the problems involved in defending the health of a population without having in mind the various elements that undermine and overpower it."

[3] See page 63 of the Journal.

The subject is treated under four general divisions, with special chapters under each. The general divisions are as follows: Internal and External Influences upon Health, Communicable Diseases, Defensive Measures against Communicable Diseases, the Urban Dwelling.

Mr. Edwin Chadwick, whose writings have everywhere won respect for their candor and practical utility, is to the author an "amiable enthusiast."

Chapters upon Air, Water, Sewer-Gas, Cemeteries, Public Funerals, Meat, Milk and Infectious Diseases are all devoted to the same line of argument; and while there is a grain of wheat among the chaff, the author often strides beyond the boundaries, not only of truth, but those of common-sense. For example, on page 113 he says: "We are forced to the conclusion that there are no better tests for drinking-water than our first parents possessed; and that the instincts, taste and experience of a committee of farmers, mechanics or intelligent housewives are more to be depended on in the selection of a public water-supply, than are the so-called scientific tests of the sanitarians."

In his belief as to the actual causes of epidemic diseases the author does not appear to have made much progress beyond the "vagaries" of Noah Webster, whose volumes on "Pestilences" (1799) he freely quotes. "Mr. Webster *thought*," says he, "that there was not much doubt that yellow fever was a pestilence among the Indians before the landing of the Pilgrims. He did not believe that it was contagious." If this is a sample of the author's scientific investigation, it is no better than that of the sanitarians whom he criticises.

He, however, apologizes for a vigorous style as follows: "If, sometimes, the author has betrayed a warmth of expression, it is because of natural indignation that he had not only been the dupe of noisy men who were posing as scientists, but that through their teachings he had been the instrument of duping others."

Vagaries of Sanitary Science. By F. L. Dibble, M.D. Pp. 462. Philadelphia: J. B. Lippincott Co. 1893.

The chief object and aim of this remarkable book appears to be to break down the doctrine of the causation of disease by filth. So far as the author refers to the popular notion that filth causes certain infectious diseases *per se* he is undoubtedly correct in his criticism. It is scarcely twenty years since Mr. Simon, the chief medical officer of the Privy Council of England, published his tract upon "Filth-Diseases and their Prevention"; but since that time the progress of scientific investigation has shown that it is not merely filth which causes disease, but specific filth, or filth in which the germs of disease have been implanted.

Dr. Dibble quotes very fully from the health authorities of all countries, past and present, in support of his views. He is especially severe in his comments upon American Health Reports, both State and local, and says he "was struck with astonishment at the almost utter barrenness, on the part of sanitarians, of anything like scientific investigation."

The files of volumes of these reports are to him a jumble of conflicting theories unsupported by fact and observation. "None of them," says the author, "(if we except the Massachusetts Board) prosecutes any researches into the etiology of epidemic disease that deserve to be called scientific."

CONSANGUINEOUS MARRIAGES.

THERE has from antiquity been a general belief, supported by some physiological considerations, that marriages between near relatives are likely to be followed by deterioration and degeneration in the offspring. It has been maintained that by such unions ancestral and family imperfections would not only be perpetuated, but raised to their highest potency.

That this holds good in the transmission of nervous diseases, no physician doubts; and the offspring of parents who are both markedly neurotic, will, unless favored by unusual fortifying circumstances, almost certainly be neuropathic.

A similar affirmation may be made regarding constitutional diseases, such as gout, tuberculosis and carcinoma.

Consanguinity and affinity have been at different times and in different parts of the world, looked upon as impediments to marriage between the parties related. The Roman law prohibited marriages between ascendants and descendants, between brothers and sisters, and at one time between cousins-German; and the old canon law and early *decretals* forbade marriages between persons as far removed as the seventh degree of consanguinity. Doubtless, on the other hand, in very early stages of society, marriages between near relatives were the rule.

The question has been asked whether, when both parents are absolutely sound and healthy, consanguineous unions are detrimental to the offspring, entailing constitutional defects.

De Sinety, in a recent work on sterility, discusses the question in the light of many interesting facts. We can, he says, only judge of the results of consanguineous marriages by the quality of the progeny. We have, to-day, at our disposal, to decide the question, a certain number of examples which seem to be exceedingly pertinent. There are certain fishing-stations on the coasts of France where the seafaring population live in the neighborhood of a rural population without contracting marriages with them. In the commune of Batz, in the Loire Inférieure, composed of 3,000 inhabitants, there has been frequent intermarrying for a great many years among near relatives of a dozen or so of families. With regard to most of them, the relationship is of the third to the fifth degree; and yet all, men and women alike, are robust, of good stature, firm health, and the children are numerous and healthy.

Many more observations of a similar nature might be cited, from which it would appear that consanguinity of itself is not especially detrimental to the progeny. As Sanson says, consanguinity raises heredity to its highest power by causing to act in the same direction *atavism*, or the disposition to revert to ancestral qualities and individual peculiarities.

If, then, the parents are vigorous, well developed physically and mentally, these qualities accumulate in their descendants and the influence of consanguinity in such an event is favorable to the species.

If the progenitors are, on the contrary, sickly, or present any pathological defect whatever, the hereditary vices of the two families are transmitted to posterity and the action of consanguinity is then detrimental.

WATER-FILTRATION AND CHOLERA.

ON another page we present a letter from Hamburg from a special correspondent well qualified to impart the information which the letter conveys. The comparative experience of Hamburg and Altona in regard to cholera last summer is interesting and important. Attention is called to the comparative immunity of Altona, for which the system of sand and gravel filtration of the Elbe water there and then practised is given credit. A similar system has lately been put in operation for Hamburg proper; and the city — of which Altona is practically a *vorstadt* or suburb — is now furnished with a water-supply similarly treated to that at Altona, and originally somewhat better. Reference is made by our correspondent to Koch's statements in regard to water-filtration and cholera. The result of Koch's investigation into this subject appeared in a paper or lecture,[1] which is exciting attention and comment in various quarters.[2]

After reviewing the situation last summer, Koch takes the ground that the difference between Hamburg and Altona in respect to cholera can be explained in no other way than by the difference in the water-supply, and that Altona was protected by the filtration of the Elbe water. He does not, however, conclude from this that a sand and gravel filter is a safe and sufficient protection against cholera or other bacilli in a water-supply. The real protection, he thinks, lay in the

[1] Zeitschr. f. Hyg. u. Infectionskrankheiten, Bd. 14, pp. 393-426; Deutsch. Med. Wochschr., No. 24, p. 577, 1893.

[2] Cholera Causation and Prevention at Home and at Hamburg, R. Thorne Thorne, M.B., F.R.S., Lancet, July 1, 1893, p. 50; July 8, 1893, p. 94.

slimy film or coating on top of the filter — a coating which consisted of the deposit of river mud, organic matter, *débris* and micro-organisms. When this coating was ultimately broken, cases of cholera were developed in Altona.

We shall undoubtedly hear more of this subject. An able engineer, small filters, and a moderate rate of filtration are recognized as three requisites for insuring good results. The new Hamburg filters are regarded as large filters.

The recent long-continued period of drought in England has called renewed attention to the best methods of treating water-supplies, and especially that of London, in regard to which a royal commission is now taking evidence, preliminary to a report.

In the mean time neither the example of Altona nor anything in the statements of Koch justify reliance upon the sand and gravel or the ordinary domestic filters *per se*, as protections against cholera or typhoid fever.

MEDICAL NOTES.

Walker Prizes. — One of the subjects for the Walker Prizes next year is "Experiments affording Evidence for or against the Theory of Evolution."

Ohio State Medical Society. — At the last meeting of the Ohio State Medical Society, N. P. Dandridge, M.D., of Cincinnati, was elected President, and Thomas Hubbard, M.D., of Toledo, Secretary.

The Birth-rate of Paris. — According to the report of vital statistics in Paris, the last week of June, there were 1,292 births, 902 legitimate and 390 illegitimate. Of these 676 were males and 616 females.

The Simmons-Tilden Law Suit. — The suit of Dr. Charles E. Simmons against the executors of the Tilden estate, for professional service, has been settled by compromise. Dr. Simmons receives $40,000 for eight years' service, his original claim having been $143,350.

Cholera. — Reports from abroad show that the cholera is making gradual progress along the whole of the Mediterranean coast of France and Spain, and to some extent northwards. At Marseilles the condition remains about the same. At Lyons there has been a slight increase in the number of cases, as at Toulon. A few cases have occurred at Nantes. In Mecca and Jeddah the death-rate has continued very high, reaching nearly 500 daily in Jeddah. In Russian towns there have been some 400 cases with about 140 deaths. The disease made its appearance in Buda Pesth on the 12th. In Alexandria there have been over 40 deaths so far.

Yellow Fever. — Two vessels arrived at Delaware Breakwater last week with cases of yellow fever on board. One was from Havana; the other from Santos, Brazil, where a severe epidemic of yellow fever exists. The deaths are reported to number several hundred; but no accurate figures have been received, and it is feared the United States Consul has died.

Quarantine Changes at Philadelphia. — The new quarantine law of Pennsylvania, which went into effect July 1st, marks an important step in the direction of a uniform national quarantine. By its provisions the control of quarantine, which is relinquished by the Philadelphia Board of Health, is given to a board of seven persons, two of whom are appointed by non-official bodies, one each by the College of Physicians of Philadelphia and the Maritime Exchange. The present lazaretto is to be removed within two years, and the new station will not be located on any mainland of the State. All quarantine fees are to be abolished. The most important feature of the bill, however, as the *Medical News* rightly says, is the provision made for the substitution of National for State quarantine. The act empowers the governor to suspend the whole State system whenever he is satisfied that an efficient quarantine is maintained by the Federal authorities. That such a quarantine will some time be maintained, can hardly be doubted, and it will be a notable reform when a single service uniform throughout all ports is established.

The Effect of High Altitudes on the Blood. — Egger has demonstrated a rapid increase in the number of red corpuscles in the blood to take place in high altitudes. From experiments on twenty-seven persons living at Arosa, an altitude of 1,800 metres, he found that though other conditions of life were as nearly the same as before, the number of red cells increased markedly from the average in these persons when at lower levels, nearly a million in a fortnight. The hæmoglobin was also increased. The gain was lasting so long as a high altitude was kept, but on returning to the plains the number gradually fell off to its original point. Koeppe also obtained similar results in his experiments.

NEW YORK.

Yellow Fever. — On July 13th, Health-officer Jenkins reported that the supercargo of the British freight steamer *Ardangarm*, which arrived from Cienfuegos, Cuba, on July 9th, had died just as the vessel was entering port, suspecting from the symptoms described to him that the case had been one of yellow fever, he ordered the body to be removed to Swinburne Island, where an autopsy was made and showed conclusively that death was due to this cause. Dr. Jenkins also reported that since July 3d, he had been holding the Belgian steamer, which came from Santos, Brazil, in quarantine, because he had no doubt that two deaths which occurred on board during the voyage were really due to yellow fever, although they had been diagnosed on the ship as intermittent fever. Both vessels, after having been thoroughly disinfected, were released from quarantine on July 14th.

ST. JOHN'S GUILD HOSPITAL. — On July 11th, the St. John's Guild Floating Hospital made its first trip of the season to the Guild's Seaside Hospital at New Dorp, Staten Island; and it is now making six excursions a week, three from North River piers and three from East River piers.

NEW YORK STATE BOARD OF HEALTH DISTRICTS. With a view to increasing the efficiency of its service, the State Board of Health has divided the State into six districts with a special inspector for each, whose duty it shall be to report the sanitary condition of the territory allotted to him and the efficiency of local boards of health. One important purpose in appointing these inspectors is to secure protection as far as possible against the invasion of contagious disease and to enable the State and local boards to take prompt and efficient action in case such invasion occurs.

MORTALITY. — During the week ending July 8th, 917 deaths were reported, an increase of 215 over the week preceding. Although this represents an annual death-rate of 25.28 per thousand of the estimated population (as against 19.37 for the previous week), this mortality is 123, or nearly 15 per cent. below the average for the corresponding week during the past five years. Deaths from diarrhœal diseases numbered 182, an increase of 97 over the week ending July 1st, and the deaths of children under five years of age amounted to 489, an increase of 149; 333 of the deaths were in children under one year, an increase of 33 per cent.; while the deaths in tenement-houses numbered 613, an increase of 58.

During the week ending July 15th, the deaths reported in the city amounted to 1,096, an increase of 179 over the preceding week. This mortality, however, is 143 below the average of the corresponding week for the past five years, and 240 below the number of deaths during the corresponding week last year. In the week ending July 16, 1892, when the weather was very hot, the mortality reached the unprecedented figure of 1,336, representing an annual death-rate of 38.09.

Miscellany.

THE CAUSATION OF ANÆMIA BY URIC ACID.

HAIG offers another chapter in his study of uric acid in a short report on experiments made to show the direct relation between uric acid excess and anæmia. The excess of uric acid, he claims, is not due to the anæmia so often found coincidently, but is its direct cause. Inasmuch as uric acid administered by the mouth finds its way, as such, directly to the blood and eventually to the urine without being changed to urea, he was enabled to alter at pleasure the uric acid percentage of the blood.

Following the close clinical resemblance between a uric acid storm as seen in the uric acid headache (migraine) and the symptoms which precede and accompany a paroxysm of hæmoglobinuria, it occurred to him by producing a uric acid storm, to try to cause at least some blood changes.

He found that by taking pure uric acid he could diminish at will the value of the portion representing the relation of hæmoglobin to red cells. This value rose again on leaving off the uric acid. Experiment also showed that the blood responded in the same way to the normal daily excretion of urates.

In chlorotic patients, after increasing the blood fraction by giving iron, he gave beef-tea, in which he had estimated the uric acid. This produced a fall of the blood fraction, which again was followed by a rise when it was left off. These observations were in several cases with results that are practically identical and apparently proportional to the amount of uric acid taken.

HEART-DISEASE OR KIDNEY-DISEASE.

TYSON, in a paper read before the Pennsylvania State Medical Society, discusses by means of four illustrative cases the difficulty of diagnosis between these coincident diseases.

The first case, that of a shop-girl, aged fourteen, was supposed to be a case of chronic parenchymatous nephritis, while further study showed it to be one of primary valvular disease of the heart, with secondary passive congestion of the kidney.

The second case was one of chronic interstitial nephritis, with hypertrophy of the left ventricle, in which all of the symptoms pointed to primary heart-disease, but the true nature of which was easily revealed upon closer study.

The third case was more complex. An ancestry and a personal history of gout; an albuminuria, at first small; absence at first of casts, and then sparse casts, all pointed to gouty kidney, a supposition by no means weakened by existing sense of oppression, and dyspnœa. On the other hand, an evident mitral murmur; moderate degree of hypertrophy of the left ventricle, dilated right ventricle; an irregular heart, gastric catarrh, and dropsy, pointed to a condition of mitral regurgitation. Yet the problem (heart or kidney?) was a difficult one. It seemed that in this case doubtless both organs were affected independently, each from the same cause — gout. Unfortunately, there was no autopsy.

The fourth case was a complete surprise in the light of the autopsy. A distinct mitral systolic murmur and extreme anasarca; scanty urine and pleural effusions, all combined to favor the idea that there was mitral regurgitation, while the fact that the patient had had two seizures, best explained on the supposition of cerebral embolism, seemed to add all that was required to make the diagnosis absolute. One symptom only might have suggested a renal origin, and that was a marked degree of hypertrophy of the left ventricle, without aortic disease, yet the autopsy showed extreme mitral stenosis and typical large white kidneys beginning to contract.

Though in many cases it is almost impossible to decide between a mitral disease and a chronic nephritis, there are certain points which are of assistance in the diagnosis: the careful study of the character of the urine and the degree of cardiac enlargement. But a fact on which the writer lays much stress in deciding in favor of a primary kidney-disease, is the failure

of heart tonics, like digitalis, to produce diuresis, even though the pulse rate is lowered. The importance of a correct diagnosis for prognosis is self-evident.

A FOREIGN BODY MISTAKEN FOR CANCER.

At the last meeting of the Lyons Medical Society, Frarier showed the stomach of a patient who had given the following curious history:

For a long time he had been losing weight and strength, and had repeated attacks of vomiting, with gastric distress. He was emaciated and cachectic. Examination showed some anasarca and a weak heart There was no cardiac murmur nor albuminuria; the stomach was much dilated; and a large diffuse tumor was felt in the epigastrium. The vomitus was coffee-colored. A diagnosis of carcinoma was made. Washing out the stomach gave slight relief; and the patient gradually failed, and died of exhaustion.

At the autopsy no tumor of the stomach was found, but the mass felt before death proved to be a large collection of prune and cherry stones and raisin pips, so matted together by mucus as to be separated only with some difficulty.

LAVAGE OF THE STOMACH.

The comparative readiness with which the stomach may be washed out by the general practitioner, and the numerous cases in which relief is thus afforded, leads Pick [1] to a discussion of what constitute suitable cases. His classification includes:

(1) All cases where the food remains an abnormally long time in the stomach, whether such delay is due to dilatation consequent on stricture of the pylorus or to simple stretching.

(2) Cases of carcinoma of the pylorus where the greatest relief is often given by regular siphonage and cleansing.

(3) To remove excessive mucous secretion due to gastric catarrh and as a means of testing the deficient elements of the digestive fluid.

Cholelithæmia and catarrhal icterus, to remove auto-organic poisons.

All cases where the retching might be fatal to the patient as in advanced cardiac, pulmonary or arterial disease are contraindications.

TREPHINING FOR PISTOL-WOUNDS.[2]

Von Bergmann reports to the Berlin Medical Society his conclusions on the treatment of penetrating wounds of the skull based on the observation of twenty-five cases. There are three easily-distinguished classes, each of which has a definite anatomical lesion, and calls for a fairly definite treatment.

The first division includes such patients as are unconscious and motionless, so that the question of paralysis cannot easily be made. Associated with this unconsciousness there are symptoms of cerebral pressure, with increasing coma; a slow followed by a rapid pulse; and a fatal termination, or gradual return of consciousness and recovery. Such cases as these point, as a rule, to an injury of the lateral ventricle, with hæmorrhage into it and the meninges.

In the second class of cases there is little or no loss of consciousness; but localized paralysis or spasms are found developing, which point, of course, to definite cortical regions.

The third class of cases is marked by absence of symptoms, the wound being seated in the frontal lobes.

As regards treatment by exploring or trephining, Bergmann takes a decided stand against undue interference, especially with the probe, which, he says, should be used only as indicated *during operation*, not to search for the bullet. The treatment of all cases should be the thorough cleansing of the parts *about* the wound, and aseptic dressing. The less interference with the interior of the wound the better. With regard to trephining, he is equally conservative. He thinks that the absorption of the clot is best done by nature, and that many cases have recovered in spite of trephining. Two indications call for trephining: the occurrence of motor irritation, and wide-spread splintering of the bone. Other cases, particularly those of the third class, call for no treatment beyond rest and cleanliness.

[2] Deutsche Med. Zeitung, 1893, No. 53.

THE TREATMENT OF PROSTATITIS BY ICHTHYOL.

Within a short time several reports have been published upon the use of ichthyol in the treatment of prostatitis. Scharff, in 1892, reported about forty cases of acute inflammation of the prostate, chiefly of gonorrhœal origin, successfully treated by the injection into the rectum of a ten-per-cent. solution in water of ichthyol, three or four times a day. An early cessation of the pain and diminution of the swelling of the gland resulted, and in no case was there any abscess formation. Ehrmann used successfully, in treating gonorrhœal prostatitis, deep irrigation with a ten-per-cent. solution of ichthyol, as well as suppositories of the same drug. Ullmann also reported excellent results from the use of suppositories. All these cases were gonorrhœal in origin.

Freudenberg,[1] of Berlin, has just reported the results of his treatment of prostatic inflammation during the last two years. His cases numbered about forty; and the treatment reported was used only in chronic prostatitis, or the later stages of an acute inflammation, since he was more satisfied to treat the active stage of a gonorrhœal or simple prostatitis by the usual routine of rest in bed and perineal applications.

In the chronic stage the treatment was always rectal suppositories, made in the following proportions:

℞	Ammonii sulfo-ichthyol . .	0.3 to 0.6 grammes.
	Ol. cacao	2.0 to 2.5 grammes.

One of these was given at night and another after evacuating the bowels in the morning. In all cases a rapid improvement took place in the symptoms. The pain on defecation, the oppression in the perinæum, and the tenesmus frequently ceased entirely, while the actual swelling of the gland was much diminished. There were but two exceptions, both cases where the treatment was interfered with by sexual excess or in other ways. In the doses given no irritation of the bowel followed, and considerably larger doses even were well borne.

[1] Centralblatt. für klinische Medicin, 1893, No. 26.

It is important, however, that the ichthyol be thoroughly mixed with the butter, not enclosed in hollow suppositories, as the crude drug is irritating enough to cause rapid evacuation of the bowel and so fail of its desired action.

THE DIRECTION OF CANCER TREATMENT.

DR. HERBERT SNOW, in a recent paper on "Improvement in Cancer Treatment," points out a few rational principles which should underlie all treatment of carcinoma, and which, if adhered to, would lead to better results than at present obtained.

The fatal effects of cancer, especially in surgical cases, are due, he points out, more often and to a greater degree to metastatic growths than to the original lesion. The "infection-paths" should be recognized as definite and regular, differing in carcinoma and sarcoma. A routine operative removal is essentially wrong. A case of carcinoma is improperly treated if the primary lesion alone be excised, while glands which are involved are neglected; indeed, the removal of glands should extend to those in the line of infection beyond the point of existing enlargement, since only thus can further progress be checked. Of the two lesions, the secondary deposit should receive the first attention if one only be attacked.

In true sarcoma, on the other hand, the presence of enlarged glands in the vicinity is *prima facie* evidence of a general systemic infection having occurred, with the probable presence of secondary growths in the parenchymatous organs. The bearing of this relation on operation is obvious.

The more we realize the force of those relations, the more urgent becomes the necessity of an early diagnosis, and immediate operation. To wait for signs of glandular infection before removing a suspicious growth is to delay too long. Microscopic diagnosis should be made at once, and heeded when made. As to medical treatment the writer says a patient with cancer not amenable to surgical operation should at once be put upon small, continued doses of morphia or opium and made permanently subject to the morphia habit, purposely induced. The drug should be given with the avowed object of arresting and keeping in check the progress of the lesion.

The benefits of the principle are most evident in connection with carcinoma in the female breast, though by no means limited to this. The practice of withholding opium until compelled by pain to resort to its use, merits unmeasured condemnation.

THERAPEUTIC NOTES.

PERSISTENT VOMITING. — Guyot[1] reports a case of persistent vomiting in a man, which resisted all the usual treatment. On the history that he had once lived in a malarial country, he was given an injection of quinine, although he showed no signs of malarial affection other than a slightly enlarged spleen. The vomiting ceased almost immediately.

DYSPNŒA OF PULMONARY PHTHISIS. — The symptom of dyspnœa in cases of pulmonary phthisis is one which especially taxes the therapeutic resources of the practitioner. Though based on physical conditions, the distress to the patient is very often out of proportion to the lesions existing in the lung. It is this sense of oppression and inability to breathe which is most difficult to relieve in many cases. Dr. Beverley Robinson, of New York, reports excellent results in such conditions from the use of an old-fashioned drug, silphium lanciniatum, commonly known as "rosinweed." He gives it in half-drachm doses of the tincture, and finds often a quick response when other drugs have failed to relieve the patient. The tincture should be made from the root, and especial care should be taken to write for the silphium lanciniatum as the allied species, thapsia garganica or silphium gummiferum, have quite different properties.[1]

A VEHICLE FOR IODIDE OF POTASH. — Delavan recommends essence of peppermint and milk as an agreeable menstruum for the administration of large doses of iodide of potash.

OTALGIA. — The recipe given below has been found useful:

℞ Menthol, Camphoræ ā . . . . . ss gr. xx.
Liq. Albolene . . . . . ʒi.
Drop in ear p. r. n.

URTICARIA. — Bourdeaux[2] has found the following prescription to give great relief in urticaria:

℞ Liquor. calcis, Aquæ Laurocerasi, Glycerini ā . . . . . equal parts. M.
Sig. Apply externally and cover with cotton.

ACNE. — Unna prescribes the following ointment for acne:

℞ Unguent. zinci, Lanolin, Calcii chloride ā . . . . . ss 10 parts.
Sulphur præcip. . . . . 3 parts.

PHOTOTHERAPEUTICS. — The ordinary sun-glass has become lately a vaunted therapeutic agent. Sciascia, an Italian oculist, reports favorable results from photocauterization in cases of trachoma, claiming more accurate and safer effects than are obtainable from other caustics, chemical or mechanical.

Correspondence.

[Special Correspondence.]

LETTER FROM HAMBURG.

WHAT IS BEING DONE TO PROTECT THE CITY AND ITS COMMERCE AGAINST CHOLERA.

MR. EDITOR: — This city is making strenuous efforts to keep out cholera, and also to prevent its springing up in the city. In respect to the former measures Russian steerage passengers are forbidden entrance into the city, and the different transportation companies are forbidden to forward them, no matter whither. In respect to the second statement, the latest result is that attained by the supply of pure filtered water. The city takes its water from the Elbe River, some distance above the harbor where also the current is quite rapid. For a considerable distance above and below this point, no vessel is allowed to anchor; the water is led into basins, where it is filtered through sand and thence is brought into the water mains of the city.

[1] La Bulletin Médical, No. 52, 1893.

[1] New York Medical Record, July 15, 1893.
[2] Rev. de Clin. et de Thér.

(The old unfiltered water-supply has been absolutely and entirely cut off.) Professor Koch has lately published a couple of articles on the action of this filtration and is inclined to believe the good results are obtained by the water passing through the layer of albuminoid matter, or slime, that is deposited on the surface of the sand, and strenuously warns against breaking up or disturbing the continuity of this layer. Whereas the water in previous years was unfiltered, dirty and suspicious, the new filter system supplies a *pure clear* article, that is germ free. Up to the introduction of this filtered water, there were scattered about the city, wooden booths where water was thoroughly boiled, and then delivered free to all who applied for it. Several artesian wells also supplied certain sections of the city. The supply of pure, filtered water being sufficient in quantity for all the city's needs, the booths are being removed. The supply of water delivered to the filter station is abundant. When it is remembered that ocean steamers come up to the harbor and here find easy berths, it is good proof that there is plenty of raw material to turn into the filter basins, and these are adequate for all needs.

Notices and placards have been posted, advising care in the use of water, so as not to overstrain the plant; but when all the basins are finished, which will shortly be the case, there will be no limit to the supply. All public parks and the streets are now being sprinkled with the filtered water.

To Americans the principal interest centres, naturally, around the treatment of the emigrants destined for the United States. There are two lines of steamers, from this city, carrying passengers to America, "The Hamburg American Packet Company" and the "Union Line." The passenger business for the latter is done by the Packet Company, so that all passengers come under the same control.

The ships carrying these passengers are cleaned and disinfected under the supervision of a medical man, who is an assistant or deputy of Dr. Jenkins, Quarantine Officer of the Port of New York. The crew's quarters and closets, the steerage compartments, closets and hospitals, receive special attention. All articles are removed; bunk-boards, wash-stands and shelving being ripped out, so that clear access is had to every part; nooks, corners and cupboards are thoroughly scraped out, as well as spaces under the bunks and drawers; with scrubbing-brush and a solution of strong soap lye and water, every part is made clean; then all is washed out with a solution of bichloride of mercury (1–500.) In the meantime, all the articles that had been removed have been as thoroughly handled on the deck, and then all are loosely replaced where they belong. Constant inspection is made during the cleaning process, until it is all completed satisfactorily. Each steerage bunk is provided, at each trip, with a new clean mattress and pillow; for each one hundred passengers, four beds must be furnished in hospitals specially set apart for this purpose.

Just before the hour of departure of a vessel, the ship is again inspected, with regard to cleanliness, air-space, and ventilation, by the sanitary inspector of the Marine Hospital Service stationed here and by the New York Quarantine Agent. At this time the officers and crew are inspected by both medical men, and the number present and inspected, compared with the muster-roll: any sick person or one showing suspicious symptoms is rejected and replaced.

The water furnished all ships is from an artesian well, which has been examined and found pure and germ free. This is the only water in use on these ships.

Every person entering the city must be registered by the police and certain hotels or lodging-houses are licensed by them to receive and care for these people. Russians have always been taken to the barracks, across the river from the city, while others seek houses where they may find people from their own section of the country. The barracks are under police control and have a physician, specially appointed to attend to the health of the inmates. Dr. Jenkins's agent makes daily inspections of the inmates and the buildings, and the sanitary inspector makes frequent visits as well. As soon as the new-comers are registered, they are stripped and receive a bath: in the meantime their clothing is disinfected by steam at a temperature of over 101° Celsius. The person remains in the bath until his clothing has remained in the steaming chest a sufficient length of time. The baggage — contents of trunk, basket or box, is taken to a steam disinfecting-plant, the day before sailing of the steamer and disinfected under the superintendence of both medical men. Inmates of the barracks must remain there under observation at least six days, before they are allowed to travel: they then receive a certificate to this effect, together with their ship's ticket and emigrant inspection-cards.

People of other nationalities are lodged, as said, in licensed houses: here they are under daily medical observation by German physicians, and also inspected frequently by the medical men before mentioned, who also inspect the hotels in every particular. People coming from infected or suspected districts are held under quarantine observation of the sanitary inspector, according to the laws enacted by Congress this last spring. These latter receive a certificate from the German visiting physicians, at the time they receive the ship's ticket as well as the emigrant inspection-cards. Every emigrant receives these cards; and those going to New York receive an additional card, as required by the New York quarantine authorities. The cards state the passenger's name, age and nationality; the name of the ship and the port of departure; and are to be daily punched by the ship's surgeons as they make their usual rounds.

At the time of embarkation, the people are gathered in one room, and then file into an examination-room, where they pass inspection. Here stand Dr. Homann, the medical inspector of emigrants, appointed by the Hamburg Government, and who stamps the official seal of the city on all tickets that pass inspection; Dr. Müller, a Hamburg physician, who assists Dr. Homann in his inspection; Dr. J. H. White, sanitary inspector of the Marine Hospital Service, who stamps the emigrant inspection-cards, required by the United States Government, with his official seal, of all persons passed; Dr. Mitchell, his assistant; and Dr. Nash, who represents the New York quarantine, and who stamps inspection-cards, of those bound for New York. The people are tallied as they pass on board the ship. In addition to the medical inspection, there is a police inspection, but that does not concern us here. Each passenger receives a ticket which corresponds to that on the ship's manifest, and which he must also show in America.

All luggage must be inspected and disinfected according to the quarantine regulations, under supervision of inspectors.

When the passengers are all inspected, the bill of health is made out, and the consul certifies to the ship's manifest, each sheet receiving the special declaration of the first officer and ship's surgeon, who have witnessed the embarkation.

Ships sailing for all ports of the United States and Canada are inspected by all the gentlemen above mentioned, and they and their luggage are treated as above stated.

I think it can be safely said that the treatment and inspection of emigrants bound for America from Hamburg is as thorough and careful a one as can be had; and no doubt it will continue to have, as has already been proved, a salutary influence on the health of such as travel to America.

Very truly yours, GEORGE W. NASH, M.D.

CELIBACY IN THE ENGLISH CHURCH. — The Diocesan conference of St. Albans, England, recently discussed the question of celibacy of the clergy. It was remarked that the livings in many cases were not given to support married men, that clergymen too often contracted improvident marriages. They were advised to follow the example of "the average doctor," who "practices continence as regards marriage until his income is sufficient to warrant such a step."

METEOROLOGICAL RECORD,

Deaths reported 3,435: under five years of age 1,633; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 897, diarrhœal diseases 574, consumption 338, acute lung diseases 250, diphtheria 130, scarlet fever 41, cerebro-spinal meningitis 40, measles 36, typhoid fever 29, whooping-cough 27, erysipelas 9, malarial fever 9, small-pox 1.

From cerebro-spinal meningitis New York 20, Chicago 5, Cleveland and Worcester 3 each, Philadelphia, Brooklyn and Washington 2 each, Lynn, Haverhill and Gloucester 1 each. From measles New York 16, Pittsburgh 8, Brooklyn 6, Philadelphia and Cleveland 2 each, Chicago and Cambridge 1 each. From typhoid fever Chicago and Pittsburgh 7 each, New York 4, Philadelphia 3, Cincinnati 2, Brooklyn, Cleveland, Milwaukee, Nashville and Charleston 1 each. From whooping-cough New York 9, Philadelphia and Brooklyn 4 each, Chicago and Pittsburgh 3 each, Boston, Cincinnati, Nashville and New Bedford 1 each. From erysipelas New York 3, Chicago, Brooklyn, Boston, Washington, Pittsburgh and Milwaukee 1 each. From small-pox New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending July 1st, the death-rate was 22.7. Deaths reported 4,496; measles 96, whooping-cough 93, diphtheria 88, scarlet fever 63, fever 42.

The death-rates ranged from 12.6 in Oldham to 41.6 in Preston; Birmingham 22.3, Bradford 24.2, Croydon 17.2, Hull 15.5, Leeds 21.8, Liverpool 37.0, London 22.2, Manchester 29.5, Newcastle-on-Tyne 17.7, Nottingham 17.7, Plymouth 28.8, Salford 26.7, Sunderland 18.2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 8, 1893, TO JULY 14, 1893.

The order assigning CAPTAIN FREEMAN V. WALKER, assistant surgeon, to temporary duty at Fort Trumbull, Conn., is so amended, as to relieve him from further duty at Fort D. A. Russell, Wyoming, and to assign him to station at Fort Trumbull, Conn., until further orders.

FIRST-LIEUT. CHARLES F. MASON, assistant surgeon, July 2, 1893, promoted, to be assistant surgeon, with the rank of Captain.

MAJOR JAMES P. KIMBALL, surgeon, is relieved from duty at Fort Clark, Texas, to take effect at the expiration of his present sick leave of absence, and ordered to Fort Marcy, New Mexico, for duty.

CAPTAIN WILLIAM H. CORBUSIER, assistant surgeon, is relieved from duty at Fort Wayne, Mich., and ordered to Fort Supply, Indian Territory, for duty, relieving MAJOR PAUL R. BROWN, surgeon.

MAJOR BROWN, on being relieved by CAPTAIN CORBUSIER, is ordered to Fort Hamilton, New York, relieving MAJOR EZRA WOODRUFF, surgeon.

MAJOR WOODRUFF, on being relieved by MAJOR BROWN, is ordered to Fort Keogh, Montana, for duty, relieving MAJOR WILLIAM H. GARDNER, surgeon.

MAJOR WILLIAM H. GARDNER, surgeon, on being relieved by MAJOR WOODRUFF, is ordered to duty as attending surgeon and examiner of recruits, at Headqrs. Dept. of Dakota, St. Paul, Minn., relieving CAPTAIN WALTER REED, assistant surgeon, U. S. A.

CAPTAIN REED, upon being relieved by MAJOR GARDNER, is ordered to report to the Surgeon-general at Washington, D. C., for duty as curator of the Army Medical Museum, and as professor of clinical and sanitary microscopy in the Army Medical School.

RECENT DEATHS.

JAMES J. LEVICK, A.M., M.D., of Philadelphia, died June 25th, aged sixty-eight years. He was one of the visiting physicians to the Pennsylvania Hospital and to the Wills Eye Hospital.

J. D. MITCHELL, M.D., of Jacksonville, Fla., died July 15th, aged seventy years.

BOOKS AND PAMPHLETS RECEIVED.

Hypnotism, Mesmerism and the New Witchcraft. By Ernest Hart. New York: D. Appleton & Co. 1893.

The Spelling of Some Medical Words. By George M. Gould, A.M., M.D., of Philadelphia, Pa. Reprint. 1893.

Nursing; Its Principles and Practice. By Isabel H. Hampton. Illustrated. Philadelphia: W. B. Saunders. 1893.

The Meaning and Method of Life. By George M. Gould, A.M., M.D. New York: G. P. Putnam's Sons. 1893.

Woman's Medical College of the New York Infirmary, Twenty-eighth Year, Annual Catalogue and Announcement, June, 1893.

Report for the Year 1892-93, Presented by the Board of Managers of the Observatory of Yale University to the President and Fellows.

The Health Resorts of Europe. By Thomas Linn, M.D., with an introduction by Titus Munson Coan, M.D. New York: D. Appleton & Co. 1893.

A Manual of Diseases of the Ear. By George P. Field, M.R.C.S., Aural Surgeon and Lecturer on Aural Surgery, St. Mary's Hospital Medical School, London. Philadelphia: Lea Brothers & Co. 1893.

A Text-book of Medicine. By Adolf Strümpel. Second American edition translated by Herman F. Vickery, A.B., M.D., and Philip Coombs Knapp, A.M., M.D., with editorial notes by Frederick C. Shattuck, A.M., M.D. New York: D. Appleton & Co. 1893.

Lecture.

TUBERCULOUS PLEURISY.[1]

THE SHATTUCK LECTURE FOR 1893.

BY WILLIAM OSLER, M.D.,
Professor of Medicine in Johns Hopkins Hospital, Baltimore.

(Continued from No. 3, p. 57.)

(b) The secondary and terminal acute tuberculous pleurisy.

HERE reference is not made to cases of general miliary tuberculosis in which the pleural membranes are involved with other parts. A miliary eruption is very often secondary to a local tuberculosis in the lung, and under these circumstances the exudate is usually fibrinous. It is interesting to note that in the 101 post-mortems from my wards, in the cases in which tubercles were found on the membranes, only four had a simple fibrinous pleurisy. On the other hand, there were eleven instances of fibrinous pleurisy in persons dead of pulmonary tuberculosis in which there was no mention made of tubercles on the pleura. This accords with the well-known experience that a pleurisy in the course of a pulmonary tuberculosis is not always due to the presence of tubercles. Acute miliary tuberculosis of the pleura, with a sero-fibrinous or hæmorrhagic exudate, was present in only seven of the autopsies. In every one of these cases was the tuberculosis secondary to some other affection, or occurred as the terminal event in some long standing illness. Whether or not in an instance, for example, of acute pleurisy with effusion, coming on in an apparently healthy individual, and which, for the sake of argument, we may presume to be tuberculous, the condition of the pleura is that of an acute miliary tuberculosis, I have no personal knowledge; but in my experience the condition has almost invariably been, as just mentioned, a secondary or terminal process in some already existing affection. The following are illustrative cases: In the first instance there was a chronic anæmia, induced by the hæmorrhoids, with old foci of caseous disease at the apices of the lungs. The death resulted from miliary tuberculosis, involving chiefly the pleural sacs.

CASE II. Hæmorrhoids; anæmia; chronic tuberculosis; caseous foci in the lungs; acute miliary tuberculosis of both pleural sacs.

R. S., male, white, aged forty-seven, admitted October 21, 1891, complaining of bleeding piles. He has always been a healthy man; never has had any illness, except the hæmorrhoids, which have troubled him at intervals for nine years. During the past few weeks they have been much worse, and he has lost blood with every stool, having had three or four evacuations every day. He says that he has lost as much as a pint of blood at one time. He has gradually become very pale. At present the hæmorrhoids are not bleeding.

Patient is a pale but well-nourished man. On admission, the examination of the lungs was negative; the heart impulse was diffuse. The pulse was regular, small in volume. The spleen was not palpable, and there was no œdema. The urine contained a faint trace of albumin, but no tube casts. He was thought to have moderate grade of anæmia from bleeding piles.

About the middle of November the patient began to be delirious, but the temperature was not high, not more than 100° or 100.5°. He had slight diarrhœa, from three to six semi-solid stools daily. He did not seem very ill, and was generally up and about and dressed, though he talked in a rambling, incoherent way.

About November 28th he began to have dyspnœa, which gradually increased. The temperature had not changed specially since his admission; had been ranging from 100° to 101.5°, and very rarely reached 102°. On December 3d the note was that he was propped up in bed: very pale; lips and mucous membranes blanched; respiration 32, labored and wheezing. Pulse 120; chest hyperresonant in front; dulness at both bases; below the angle of scapula an absence of breath sounds. There was no expectoration. He continued to have three or four loose stools daily, and died on the 5th.

Autopsy. Large, well-built, well-nourished man, marked anæmia. Peritoneum is smooth. Over the mesentery, and the lower surface of the diaphragm, and in the pelvis, there are numerous elevated, translucent tubercles, some of them surrounded with areas of hyperæmia. The peritoneal surface of the intestine also presents numerous tubercles. The surface of the spleen and the contiguous diaphragm presents many tubercles.

Acute miliary tuberculosis of both pleural sacs, with about two litres of serous fluid in each. The membranes were covered with a thick, fresh fibrinous exudate, after the removal of which many miliary tubercles were seen. Both lungs were compressed; no cavities; but at the apices there were old and partially softened caseous masses, with many miliary tubercles. In the lower lobes there were only a few scattered tubercles. The spleen presented a few tubercles; no tubercles seen in the liver.

Intestines. One or two small ulcers, with irregular margins in the ileum. The mesenteric glands hard and caseous.

Meninges were œdematous, but presented no tubercles.

In the following instance the patient died of an acute entero-colitis, with an acute miliary tuberculosis of the pleura as a terminal event.

CASE III (abstract). Chronic entero-colitis; acute tuberculosis of the left pleura.

Jos. A., aged thirty-three, colored, admitted January 23, 1891, complaining of diarrhœa and colic. There was no history of tuberculosis in his family. He had gonorrhœal synovitis five years ago, and a chancre. For nearly a year he has been subject to diarrhœa. On admission, patient was emaciated and anæmic; afebrile. The physical examination was negative. He had four or five stools daily, yellowish white in color, and contained undigested food; no amœbæ were found. He was very anæmic, had moderate fever, temperature range from 90° to 100°. The diarrhœa was uncontrollable, and he gradually sank, and died on February 28th. There was found an extensive entero-colitis, chiefly of the large bowel, with irregular ulceration. Almost the entire costal pleura on the left side was the seat of an extensive eruption of miliary tubercles, quite fresh, with hæmorrhagic zones about them, and much fibrinous exudate.

[1] Delivered before the Massachusetts Medical Society, June 13, 1893.

These fresh adhesions extended along the diaphragmatic surface. The bronchial glands were caseous. There were no lesions in the lungs, except at the edge of the lower lobe, adherent to the diaphragm, there was a firm caseous mass, with some induration about it and colonies of miliary tubercle.

Post-mortem, we certainly see acute miliary tuberculosis of the pleura most frequently in the bodies of persons who have been under treatment for some chronic malady, affections of the heart and arteries, chronic Bright's disease, or scleroses of various sorts. Usually there will be found in these cases old foci of tuberculous disease, a caseous nodule at the apex, or in the bronchial glands, or in the mesenteric glands. Of late, attention has been called repeatedly to the association of tuberculosis of the serous membranes, most commonly of the peritoneum, with cirrhosis of the liver; but a number of instances of terminal tuberculosis of the pleura have also come under my care in this disease, and it may exist without having caused symptoms enough to attract attention. In one of my wards at Philadelphia Hospital an elderly man, with cirrhosis of the liver and moderate ascites, with dulness at the right base, died suddenly of hæmorrhage from the stomach. The effusion on the right side, which we thought to be hydrothorax, as it had come on without any special aggravation of the symptoms, proved to be acute miliary tuberculosis, with effusion. More frequently the symptoms are pronounced, as in the following case:

CASE IV. Fatty and cirrhotic liver; hæmorrhage from the bowels; bilateral acute tuberculous pleurisy.

Mrs. L., aged twenty-seven, admitted with hæmorrhage from the bowels and tenderness over the region of the liver, which organ was slightly enlarged. There was no jaundice. She was a hard drinker, and had been in failing health for some months. Signs of pleurisy were discovered on both sides, and she had a severe cough. She sank rapidly, and died within a week or ten days after her admission.

Autopsy. Left lung covered with a thin, fibrinous exudation, thickest at base and near the edges. In places, the membrane is studded with minute granular tubercles, which are best seen where the exudation is less abundant. The organ is crepitant throughout, a caseous spot is seen at apex, and a narrow fibroid area in the lower lobe. No disseminated tubercles throughout the substance. The right pleura presents a similar exudation, less abundant than on the left side. The costal pleura is thickly lined with false membrane, is congested, and presents small gray bodies scattered through the membrane. At the apex of the lung is a small caseous mass, with a cavity the size of an almond, in direct communication with a bronchus. In the neighborhood of this are several small groups of tubercles. The lower lobe also presents a couple of small caseous bodies, but no scattered tubercles. Liver weighs 2,200 grammes, is large and pale. Lobules distinct, bile-stained in centre. Organ is both fatty and cirrhotic. Other organs normal.

Such instances as the following are not rare in old hospital patients with cardio-vascular and renal changes. More than once I have mistaken a terminal tuberculosis of the pleura for hydrothorax.

CASE V. General arterio-sclerosis; primary tuberculosis of right pleura.

Joseph A., aged seventy, colored, laborer, admitted July 26, 1892, complaining of shortness of breath and swelling of the feet. No family history to be obtained. His wife states that he has been a perfectly healthy man all his life. She never heard him say that he had any illness. With the exception, some years ago, of a gathering under the left arm, he has been perfectly well. He denies the use of alcohol to excess.

His present illness began suddenly four weeks ago with a shaking chill, which lasted about half an hour, and was followed by pain in the stomach and shortness of breath. He has had no return of the chills, but has complained of abdominal pain. Two weeks ago the legs began to swell, and he thinks the abdomen was also slightly swollen. For about the same length of time he has been a little irrational. There has been slight cough, and he has had to sit up in bed to sleep.

Present condition. In bed, lying on the left side. He is somewhat emaciated; respiration rapid, 48; pulse 136, easily compressible, radials calcified; temperature 101°, rose in the night to 102.5°. He is not rational, and constantly mutters to himself.

Thorax. Resonance throughout the right front is good, but rather tympanitic; in the upper left front it is full, and somewhat tympanitic in character. Respirations everywhere accompanied by an expiratory groan, and in front they are harsh, and there are occasional râles, which, on the left side, are medium-sized. Behind the resonance is impaired at the right base, clear on the left side; on both sides respiration is harsh, and accompanied with fine, moist râles. Heart impulse is in fourth, fifth and sixth spaces; maximum in sixth, three centimetres outside the nipple line. Relative dulness at third rib. Sounds are feeble and heard with difficulty.

Patient was taken home August 11th; the dilatation of the heart had subsided under the use of digitalis. He had slight diarrhœa, which was checked with alum enemata. The signs of engorgement in the lungs disappeared and he had no pulmonary symptoms. The case was regarded as one of hydrothorax, secondary to the dilated heart in chronic arterio-sclerosis. Death occurred about two weeks after he left the hospital.

Autopsy (Dr. Flexner and Dr. F. R. Smith, abstract). The patient was found to have general arterio-sclerosis, with hypertrophy of the heart. The pericardium was smooth. The right pleura was thickened and the pleural layers uniformly adherent. The costal membrane measured about four millimetres in thickness, and was covered with tubercles, somewhat larger in size than miliary granules, and, as a rule, caseous. The underlying thickened infiltrated tissue was yellowish, and consisted of a diffusely caseous mass. The outermost layer was more fibrous. The pleura covering the diaphragm was greatly thickened and infiltrated. The lung was somewhat compressed, deep salmon color, and contained no tubercles. The left pleura was not especially thickened; no adhesions. There were small miliary nodules, however, on the visceral layer. The apex of the lung was somewhat retracted, and on the anterior edge of the upper lobe there was an area of caseous pneumonia, with a small central cavity. There were, however, a few scattered tubercles throughout the posterior part of the lung.

(*c*) *Acute tuberculous suppurative pleurisy.*

A considerable number of the purulent pleurisies, designated as latent and chronic, depend upon tuberculosis, but the fact is not so widely recognized that acute ulcerative and suppurative disease, of a most severe

type, may occur and run a very rapid course. In the following remarkable case the disease attacked a young, healthy woman of good family history, and set in abruptly with a chill and severe pain in the side. On admission there was dulness in the right side, feeble breathing, but there were features about the physical examination which made us a little uncertain about the nature of the case, and nothing was obtained on several aspirations. Within a few days, however, it seemed so clear that suppuration must be going on that Dr. Halsted was requested to operate. Instead of finding any large collection of pus there were small pockets varying in size from a marble to a chestnut, and though portions of ribs were resected in three different places no large collection was found. The symptoms persisted, and death took place about five weeks after the onset of the illness. Remarkable ulcerations were present throughout the right pleura, with pockets of pus between the adherent layers, no large accumulation, and an extensive acute miliary tuberculosis of the lungs. The tubercle bacilli were present in large numbers in the pus. Full details of the case are as follows:

Case VI. Suppurative tuberculous pleurisy; numerous pockets of pus; operation without benefit; miliary tuberculosis of lung.

Lizzie W., aged twenty-one, German by birth, was admitted to ward G, April 7, 1893, complaining of chills, fever, and pain in the right side.

Father and mother living and well; one sister living; no history of hereditary disease in the family.

She has always been a perfectly healthy girl. Has been in service; has only been in this country a short time. She had erysipelas of the head and face some months ago, and has not been quite so well since. She was seen by Dr. Salzer, who found signs, he thought, of effusion at the right base with high fever, and he ordered her removal to the hospital.

Present trouble began, she says, fourteen days ago with pain in the right side and fever. She had a chill about six o'clock, and had a sweat at night. The pain was of a dull character, and much aggravated on drawing a deep breath. There was no cough. The fever, pain in the side, and sweating have been the chief symptoms throughout her illness. She has been unable to work since its onset. The appetite is poor, and she has lost considerable in weight.

April 8th. Present condition. Small-framed, well-nourished young woman. Lips and mucous membranes of a good color; tongue slightly coated. Temperature on admission was 101°; this morning, at 10 A. M., it was 102.5°; pulse 88; respirations 28. Chest is well formed; good costal angle; both sides expand well; the right much less than the left.

On percussion there is flatness on the right side from the fourth interspace in parasternal line; from the fifth rib in mammary line; from the sixth in anterior axillary line. At the back there is flatness below the angle of the scapula. The breath sounds are clear in the infra-clavicular region, and as low as the nipple. Below this, behind and in front they are feeble, though clear. Behind, over the flat areas, respiration is feeble and distant. The vocal fremitus is absent over the flat areas. There seems to be a slight movable dulness at the level of the nipple in front. The cardiac impulse is in the fourth interspace in normal position. The sounds are clear, and of normal relative intensity. The abdomen is negative. The liver dulness reaches to the costal margin; the border was not palpable, and there is no pain on deep pressure. The urine is whitish yellow acid, 1,020; no albumen. It was thought probable that the case was one of empyema, and on the 10th an exploratory needle was inserted in the fifth space in the anterior axillary line, but nothing was obtained. The temperature range during the next week was very irregular, reaching sometimes to 104° or 105°. She had chilly feelings and heavy sweats at night.

On the 11th the following note was made: Pulse 130, regular, soft; she is propped up in bed; respirations are quiet. Patient lies somewhat on the right side. The left side of the chest moves freely. On percussion and palpation there is great tenderness over the sternum, particularly at the third right interspace and at the sternal end of the fourth costal cartilage. The line of dulness begins at the fourth space at the sternum, and passes through the nipple. The flatness extends across the sternum. Lower border of the liver is not palpable, but the flatness extends in the nipple line to costal margin. The respiration above the line of flatness is clear, below feeble, distant, and difficult to hear. Vocal fremitus, while practically absent in front, is to be felt in the axilla. In the back the line of flatness has not materially changed from that noted on entrance. On auscultation, as one approaches this line, there are fine, moist râles on inspiration, which are increased by coughing. The apex beat of the heart is not dislocated outward.

An exploring needle was again introduced; this time at the eighth space below the angle of the scapula, but with a negative result.

On the 12th the temperature was 105°; the pulse this morning was quieter, only 80 to the minute; tongue was not dry. There was to-day extreme sensitiveness along the right margin of the sternum, particularly in the third and fourth interspaces. The blood count gave over 5,000,000 red to the cubic millimetre, and 18,000 white.

It seemed evident that there was suppuration going on in the chest, and it was thought most likely to be an empyema, possibly diaphragmatic. The possibility also of a subphrenic abscess was considered, though this did not seem to be very likely, as the liver was not depressed. The points which made the case somewhat dubious were the extent of dulness and signs of effusion without marked dislocation of the heart apex, and without anything like a typical line of dulness and not of movable character. The absence of fluid also, on aspiration with a good-sized exploring needle, suggested that there was something unusual.

The case was transferred to the surgical department and on the 13th, Dr. Halsted operated.

Under ether an attempt was made to find the abscess cavity by means of an exploring needle, which was thrust into the right side of the chest in several places, where dulness was marked. Then a portion of the fourth rib over the painful spot was excised, and only a small pocket of pus found; portions of the sixth and of the eighth ribs were also removed, but only small areas of suppuration within the pleura were seen. The wounds were stuffed with gauze, discharged for a time freely. Tubercle bacilli were extraordinarily abundant in the pus. The patient died early on the morning of May 8th.

Autopsy (Dr. Barker). Body somewhat emaciated. Scars of the incisions mentioned above, and two of them had slight sinuses. On making the preliminary

median incision, pus oozed from beneath the skin over the sternum. On stripping back the skin, fistulous sinuses were seen close to the edge of the sternum in the second and third and fourth interspaces.

Thorax large; costal angle wide. Right pleural cavity has been largely obliterated, the visceral being intimately adherent to the costal pleura; both layers grayish-white in color, thickened and infiltrated. Over the lower lobe it is in places fully two centimetres in thickness, and it is adherent to the diaphragm. Tubercles have grown through the diaphragm and appear on the peritoneum. On this diaphragmatic surface of the pleura, there are a number of abscesses filled with greenish pus and cheesy material; the walls are lined with necrotic tissue. In front, between the pleura and the diaphragm, corresponding to about the seventh costal cartilage, there is a large recent abscess the size of a hen's egg, which has infiltrated the diaphragm and made an ovoid identation on the surface of the liver. Several of these intra-pleural abscesses exist along the spine, and have eroded slightly the bodies of the vertebræ. Here and there over the surface of the middle and upper lobes, between the layers of the thickened pleura, are recent abscesses, varying in size from a marble to a walnut. The whole lung is thickly studded with minute miliary and sub-miliary tubercles, gray and translucent.

On the left side there are no adhesions, and beneath the pleura there can be seen a few minute miliary tubercles, which are thickly set throughout the lung substance. The pleura is not at all thickened. The bronchial glands are somewhat enlarged, deeply pigmented and thickly studded with tubercles. The pericardium presents a few small miliary tubercles; no exudation. There is a small miliary tubercle on one leaflet of the mitral valve. The spleen is enlarged and soft, weighs 445 grammes and presents many miliary and sub-miliary tubercles. The same are present throughout both kidneys. In the ilium, Peyer's patches are reddened, and in some there are minute grayish-white and yellowish-white miliary nodules. The mucous membrane of the ilium, just above the valve, is completely studded with tubercles. Some are softened and breaking down, and there are slight superficial losses of substance. The mesenteric glands are somewhat enlarged and hyperæmic. There are also pale yellow areas. The glands along the aorta are enlarged, and many of them caseous. The glands along thoracic aorta are also enlarged and caseous. The cover-slips from the pus in the pleura show large numbers of tubercle bacilli. Agar Esmarch's tubes, made from the pleural pus, spleen, liver and kidneys, remain sterile.

2. *Subacute and Chronic Tuberculous Pleurisies.*

There are two groups of cases, with effusion, and the chronic adhesive form, the former being by far the most numerous.

(*a*) *With Sero-fibrinous Effusion.*

The process may be primary, or, at any rate, most extensive in the pleura, or secondary, to manifest tuberculosis of the lungs.

The primary constitutes an extremely important division of the tuberculous pleurisies, and here may be reckoned a not inconsiderable number of all the cases of the insidious form. The true character of the disease is frequently overlooked, and indeed for a long time there may be nothing positive on which to base a diagnosis. Though we speak of the disease as primary in the pleura, in almost every instance there are tuberculous foci in the lungs or in the bronchial glands, or the process has extended from the peritoneum. Frequently the cases are admitted to the hospital with acute manifestations, but with advanced pleural lesions evidently of long standing, and antedating the pulmonary tuberculosis. The following are illustrative cases:

CASE VII. Bilateral tuberculous pleurisy; acute tuberculosis.

Henry W., aged forty-three, admitted July 29, 1891. Rather more than a year ago, patient was in hospital for jaundice and was discharged well. He returns complaining of cough and shortness of breath. He states that his present trouble began about four weeks ago; he woke up in the night with shortness of breath; has had chilly feelings, though no rigors and had felt very weak. He has had some cough, very little expectoration, no pain; no œdema of feet. He does not think that he has lost any in weight. Temperature on admission was 102°; the following morning 103°; pulse 128; respiration 36. The urine is dark yellow in color, clear, no albumin; Ehrlich's reaction not present.

The chest is broad and deep, expansion fair, a little more on the left than on the right. Percussion is clear on the right side at the apex, and to the fourth rib; below which there was impaired resonance. On the left side a clear note to lower border of second rib; dulness from the second to the fourth, and from the fourth rib in axilla there is flatness. Defective resonance over the central portion of the lung behind and flatness at the base. In the left lung there are numerous râles at the apex, with pectoriloquy, and behind distant tubular breathing. Breath sounds are almost absent at the left base. On the right side there is flatness at the base, with distant tubular breathing. Effusion was suspected at both bases, and he was aspirated in the eighth right interspace behind, and a small amount of hæmorrhagic effusion found. On the following day he was aspirated at the eighth left interspace behind, and a few c. c. of fluid (hæmorrhagic) removed. The sputa contained tubercle bacilli. The temperature was high, from 103° to 104.5°. He became delirious, had rapid breathing, blueness of the finger-tips developed, and the pulse became much enfeebled, 130, and he died on the morning of February 4th.

Autopsy (Dr. Councilman). Large, well-developed, well-nourished man; circumference of the thorax in nipple line 93 centimetres.

Left pleural cavity partially obliterated by old adhesions, especially at the apex and posteriorly. The remainder of the cavity filled with about 300 c. c. of turbid, yellow serum with flakes of fibrin. Both layers of the pleura much thickened by a new gray vascular tissue, and covered with a gelatinous fibrin. There are many opaque white nodules beneath the membranes, and the thickening is marked. The layers can be peeled off as a continuous membrane, and beneath them can be seen opaque yellow and gray miliary tubercles. The right pleural cavity presented old adhesions only at the base, and it contained 350 c. c. of sero-fibrinous fluid, the surfaces covered with fresh gray fibrin; the pleura and the membranes slightly thickened.

The pericardium was smooth; heart presented nothing abnormal.

Lungs. At the apex of the left lung there is an irregular cavity measuring three by five centimetres, the tissue about it in a condition of gelatinous and tuberculous pneumonia. There are clusters of tubercules and miliary granulations scattered throughout the rest of the lung. The right lung presents a few scattered miliary tubercles without any very large areas of consolidation.

A few fine miliary tubercles were found in the kidneys; mesenteric glands presented a few small tubercles.

The condition of the pleura here antedated evidently the more acute onset of his final illness, and he was probably the subject of a latent tuberculous pleurisy, followed by a general infection.

Case VIII. Chronic tuberculous pleurisy with effusion.

E. S., male, aged thirty-one, colored, admitted January 12, 1891, complaining of cough, pain in the right side, and dyspnœa. He has had cough at intervals for a year; no hæmorrhage. About Christmas of last year he got very much worse, and since then has had high fever, night sweats, dyspnœa, and abundant expectoration. His family and personal history are good.

He is well-nourished; face, lips, mucous membranes and finger tips are cyanosed. Temperature, 102°; pulse 128; respirations 54. On the left side there was dulness from the second rib, and the heart was pushed over to the right side. He was aspirated and twenty-seven ounces of fluid removed. After aspiration, the chest was clear to the lower border of the third rib, below that dulness shading into flatness at the base. The temperature range was high, 102° to 104°, and he had a good deal of cough. The patient was aspirated again on the 23d, and one litre of fluid removed. The sputa was examined repeatedly, with negative results, until the first of February, when bacilli were found in moderate numbers. The fluid did not re-accumulate to any extent. Very marked defective expansion on the left side. Breath sounds were clear on the right side; fremitus was present on the left side to the base, though the dulness was still very marked, and distant tubular breathing with fine râles. The note states that there was no diffuse, general bronchitis, such as might occur with an eruption of miliary tubercles. Pulse became rapid; he had delirium; the temperature kept high until the 31st, and it fell to 98° on the 3d, when he died.

Autopsy (abstract). Right pleura adherent over entire extent; firm. Left pleural cavity contains about 1,200 c. c. of slightly turbid serum. Left lung compressed, tough, leathery, dark red; adherent posteriorly along the spine; lower lobe presented several firm tubercles. The pulmonary and costal pleural layers were thickened and tuberculous. Right lung presented, in the upper lobe, numerous firm, gray tubercles and caseous areas. At the apex a small cavity about two centimetres in diameter. The lower lobe was very œdematous. A few miliary tubercles scattered throughout the lung. Small ulcer in the left vocal cord. No tubercles in the liver or spleen; one small tuberculous ulcer in the intestines.

More commonly the pleurisy sets in insidiously, and is the most prominent feature in the case. There may be no suggestions of tuberculosis, but in some instances the history of a previous attack or of hæmoptysis may arouse suspicions. After aspiration the fluid re-accumulates, and repeated tappings may be necessary. The patient regains a certain measure of health, with greatly thickened pleural membranes, and persistence of the dulness on the affected side. When these cases are carefully followed, a certain number of instances develop unmistakable pulmonary tuberculosis, or they die of a general infection. The following illustrative cases are of interest, from the fact that they were under observation for longer periods than is usual in hospital practice.

PHAGOCYTOSIS.[1]

BY HAROLD C. ERNST, M.D.

The idea of presenting a paper upon the subject of phagocytosis suggested itself to me some time ago; for it had seemed to me, from certain incidental conversations, that perhaps too little attention was being paid to facts that are being brought out in connection with it.

This idea has been strengthened by the publication of the volume upon "La Pathologie Comparée de l'Inflammation," containing the lectures by Metschnikoff, delivered at the Institute Pasteur two years ago. Of course, much has since been done, but, so far as the facts there related have to do with phagocytosis, this work is in very much the direction of that which preceded it, and a short review of the whole subject does not seem to be uncalled for.

This book of Metschnikoff's appears to mark an epoch in comparative pathology, and yet very little attention has been paid to it. Although, as the author says, the theory of phagocytosis is not explained in its entirety in it, nevertheless there is enough of the subject included to amply repay the labor of perusal, to those who are interested.

Before coming directly to the subject matter of the paper, a few words of explanation are necessary.

Ever since the knowledge of the infectious diseases was so enlarged as it has been by bacteriological studies, explanations have been sought of the methods by which bacteria are disposed of in the living animal tissues when they have once effected an entrance; and equally has a solution of the phenomena of immunity, either natural or acquired, been searched for. These phenomena can depend only upon some property of the tissues attacked, that renders them an unfavorable soil for the development of the bacteria seeking to gain an entrance — a fact that is easily proven by the *toxic* effects of sterilized cultures when introduced into animals that are insusceptible to the effects of the living bacteria, from which these cultures are derived.

As offering some explanation of the facts that are matters of common knowledge — the conditions of immunity and the commoner ones of recovery from infectious disease — there have been a number of theories advanced, and supported with more or less vigor and ability.

The bacteria are known to produce their effects in

[1] Read before the Boston Society for Medical Improvement, April 10, 1893.

several distinct and definite ways: (1) by mechanical obstruction pure and simple; (2) by abstracting from the tissues of the body the material necessary for their own development, and, by so much, depriving the tissue-cells of nutrition necessary for *their* development; (3) by the production, during their growth, and, either by direct exciting metabolism, or, as the result of the chemical affinities of the elements left in unstable equilibrium after those necessary for the bacteria have been abstracted, of new chemical compounds that are destructive to their own further activity, or even to their further existence.

These processes being generally known to occur — the actual destruction of the bacteria or the limitation of their activity, going so far, as to make this latter none at all — have been explained upon several grounds.

Immunity — using the term generally, to express *any* degree of limitation of the activity of bacteria — has been explained upon the ground that (1) the bacteria during their growth in the living tissues, produce the loss of some material in the tissue-cells that is necessary for bacterial development, and that this loss is not supplied to the tissue-cells for a definite period of time, this time varying in length and covering the period of "immunity" of the individual organism against that special disease. This supposition is purely theoretical and very little evidence of any kind has been brought forward to defend it. (2) The bacteria are supposed to produce, during their development, and in the same way as they produce the elements hurtful to the tissue-cells, certain other elements, or rather compounds, that are destructive to their own development and existence, and that these new compounds, the result of bacterial development, are eliminated from the living organism only slowly; so that during their elimination and during their presence only, the organism is protected against a second invasion of the bacteria — in other words, for that length of time is immune against a second attack of the disease. If this supposition be correct, and if these substances are the result of the development of the bacteria, it offers no explanation of the existence of these immunizing substances in animals *naturally* immune to any special disease — at least, no more explanation than that offered by the immortal "Topsy" for her own existence, "she growed." Nevertheless, a reference to Behring's latest publication, "Die Blutserum Therapie," in which his theories in regard to the occurrence of immunity are elaborated, will show that there is a strong tendency to neglect, in the light of the more recent researches, all that has gone before, or, if the suspicion may be given expression, much that has not been done in Germany. The author, in seeking to show the various methods that have been adopted for procuring immunity, gives the following tables, that furnish a satisfactory summary of the subject:

I. Showing the method of action of the agent producing immunity. It occurs (1) by the destruction of the living cause of the disease; (2) by hindering the growth of this living cause; (3) by the destruction of its infectious properties (which result, according to Behring, is effected by the taking away from the bacteria, of their power of producing their poisonous products); (4) by the destruction, in the infected organism, of the poisonous material produced there; (5) by such a change of the central organs or of the living cells, that they obtain a higher degree of resisting power against the nerve toxines and cell toxines produced by the bacteria.

II. The conditions necessary for the production of immunity are as follows: A, a passive state of the organism (exhaustion theory and the theory of non-favorable culture medium); B, a functional state of the organism, divided into (1) a function of the living condition of the organism (the contest theory), and (2) a function of the dead condition of the organism.

The question of whether phagocytosis plays any part in this process is completely ignored, unless it be what is meant by the expression "the contest theory"; and certainly no stress is laid upon it, nor is it considered in any of the statements made during the course of his book.

So much and so excellent work has been done upon this part of the subject, however, that it is not possible to ignore it entirely — as many of the workers of to-day are inclined to do — and even with the brilliant results that have been reached by methods, of which phagocytosis probably does not form a part — exemplified in this work upon "Blood-serum Therapeutics" of Behring and others, there remain many processes occurring in the natural course of disease, in which this especial property of the cells must be reckoned with.

The theory of phagocytosis is simply this — that in many of the processes that follow the introduction of bacteria into living tissues, certain cells of the fluid and solid tissues of the body act as actual phagocytes; they possess the property of collecting about the invaded region, and of englobing and destroying, by absorption, the living bacteria, that without their interference would flourish, gain access to other portions of the organism, and produce an attack of an infectious disease.

The cells that are possessed of this power, do not, as is often stated, come solely from the leucocytes (the white blood corpuscles), but under certain conditions and in certain diseases, perhaps in all, some at least are produced from the fixed cells of the surrounding tissue; and in such case they have characteristics that make them easily recognizable.

One of the first results of experimental work that called attention to this englobing property of certain cells seen in inoculation experiments, was that following the employment of injections of anthrax bacilli in animals that were susceptible and in those that were insusceptible to attacks of the bacilli. In the first case, that of the susceptible animals, few leucocytes were found at all, and those that were present were not found to contain any bacteria; in this case the micro-organisms were found in enormous numbers in the blood-vessels, but lying free in the blood-current. An entirely different appearance presented itself, however, when the same bacteria were injected into animals that were immune to their attacks. In this case, there was found a much larger number of leucocytes, and they were seen to be crowded with large numbers of bacilli; whilst none, or almost none of the bacteria were to be found in the blood-current or in other parts of the body than that in which they had been introduced. This appearance was found to be present, not only in animals that were possessed of a natural immunity to anthrax, but in those that had been made artificially immune as well. The natural sequel, therefore, was that this complete contrast should have attracted attention, and should have been seized upon

in order to explain, not only immunity pure and simple, but the destruction of the bacteria in the body and the recovery from an infectious disease as well.

It is to Metschnikoff that the first statement and amplification of this theory is due (and, lately, to certain of his followers and proselytes also); and his assertions have been supported by the most brilliant series of minute and painstaking investigations of recent years.

Starting with known observations, made during many years upon unicellular organisms, he sought to apply the results of these observations to the single cells of more complex beings. It has long been known that the unicellular plants are capable of englobing granules of pigment, which remain for a longer or shorter time in their interior, and that soluble substances, taken up in the same way, would disappear gradually, and that it is in this way that nutrition is obtained. Observations were further made, showing that in not exceptional cases, these same single-celled organisms were capable of englobing living bacteria, and that bacteria thus taken up would gradually disappear in the same way as did the particles of nutritious material; the characteristics of this disappearance being a gradual paling of the rod, a granular appearance, and finally its complete fading from view.

These phenomena were seen to be of regular occurrence, not appearing as variations and unusual accompaniments of special conditions; they were distinctly a provision of Nature for the nutrition of the amœbæ, and for their protection against the attacks of hurtful agencies.

At the same time, the action was so similar to what has already been said had been observed in the case of animals immune to anthrax when inoculated with the bacilli of that disease, that it was inevitable that a comparison should be drawn between the two, and a similarity of action sought to be established. To carry out the idea, the living tissue is to be looked upon as a collection of single cells, certain of them endowed with the power of independent action under certain circumstances. Under most of the conditions of vitality, of course, there is, and must be, a certain oneness of life, necessary for the higher vitality of the organism of which they are but constituent parts; but under exciting force of differing kinds this unity is done away with, and to some classes of these cells of living tissue is ascribed the duty of protection and repulsion that may be carried out in various ways.

Therefore, the fundamental idea of phagocytosis is that living multicellular tissue is to be looked upon as a collection of single cells capable of individual action, in classes, under special circumstances. This being the case, it remained to show if any of the cells of complex tissue had this power of independent action; and the question did not need to be asked long before an affirmative answer could be made. In fact, it had already been made, in the researches of Cohnheim and all his followers, upon the migratory powers of the white blood-corpuscles in response to any irritation of the hurtful kind; and all that was at the time known in regard to these bodies was in the nature of a prop of any theory that explained this responsive action by a tendency towards resistance to an invasion of hurtful elements. But at first the idea was that their migration was simply for the building up of a protective wall against the further advance of the attacking force, the nature of which was not at all understood until modern methods of bacteriology came into use. Then only, did the conception occur, that there might be something more in the part played by the leucocytes than a simple negative opposing force, and the development of this conception led to the experiments upon phagocytosis.

Metschnikoff's first paper upon the subject was published some ten years ago, and has been followed rapidly by others in the same direction, until the mass of material that he has collected is enormous, and absolutely astonishing to one who becomes familiar with it for the first time. The literature this experimenter has produced is scattered through the pages of many journals, both French and German, although of late years most of his original work is to be found in the volumes of the *Annales de l'Institut Pasteur*.

As applied to the complex, multicellular organisms, much of the original work was done with the bacillus of anthrax, both in its full strength and in an attenuated condition, and the experiments were conducted upon *both* warm- and cold-blooded animals — in the former case upon rabbits, guinea-pigs, and rats, and in the latter upon daphnia, other small animals, and especially upon frogs. With the latter, many of the experiments were, of necessity, made upon them at a temperature above that at which they ordinarily lived; and while, at their normal temperature, they are insusceptible to the action of the anthrax bacilli, this immunity disappears when their bodies are raised to such a temperature as will permit of the development of these bacilli. According to Metschnikoff, the immunity at the lower temperature is due, not alone to the unfavorable condition for the growth of the bacilli, but also to the phagocytic action of the white corpuscles, which at this temperature — their normal one — are found to be full of the bacilli, a fact which is not observed when the animal is raised to a higher temperature and becomes susceptible to the disease; he explaining this susceptibility by the hindrance to the action of the white corpuscles by their unnatural temperature, whilst Baumgarten remarks that frogs raised to such a temperature would die anyhow, but omits to state how this occurs so early as is the case after inoculation with anthrax bacilli.

The experiments, however, were not limited to work with the virus of anthrax, either attenuated or of full virulence; but investigations have been made upon many other diseases, notably chicken-cholera, tuberculosis (as a type of a chronic inflammation), septicæmias of various kinds, and serous inflammations. In the latter forms of reaction, it is true that very few cells possessed of phagocytic action are to be seen; but, as Metschnikoff says, it is equally true that these forms of inflammation are as yet but incompletely understood, and if, because a thing has not been seen, its existence be absolutely denied, an unscientific conclusion would be reached.

As a result of all this work, which has been supported by what Metschnikoff considers as of equal importance, the pursuit of similar studies upon invertebrates as well as vertebrates, the general conclusion has been reached from the observed phenomena, that, in nearly all (if not all) of the infectious diseases, an important part in the destruction of the invading bacteria is played by certain individual cells endowed with phagocytic powers. Many interesting properties of the cells of animal tissues have been brought out as well.

In the first place, it seems to have been definitely

determined that the phagocytic power is not confined by any means to the leucocytes, derived from the white blood-corpuscles, but that the single nucleated cells of a larger size than the ordinary multinuclear bodies commonly seen in any purulent exudation are derived from some of the fixed tissue elements in the neighborhood of the reacting locality. These are the "macrophagocytes," which are always possessed of a single nucleus, and are usually larger than their neighbors, and are so called to distinguish them from the "microphagocytes" that are multinuclear and are derived from the leucocytes or white blood-corpuscles; the main distinction in all cases being the possession of more than one nucleus, and not the size, which may vary very slightly. (The further division of the leucocytes may be found in Metschnikoff's book on "Inflammation," p. 131.) These macrophagocytes are possessed of the power, under certain conditions, of englobing and destroying the microphagocytes as well as bacteria; and in those cases in which they are freely formed, seem to have more active phagocytic properties, as against bacteria, than have the microphagocytes. In a comparatively recent work, Metschnikoff also describes the formation of phagocytes from the invaded muscular tissue, to which he has given the name of "myophagocytes."[2]

Another of the exceedingly important properties of the cells, that these recent investigations has brought out, is that of "chemiotaxis," which is the property that movable cells have of responding to irritation of any kind — either chemical, as in the case of simple chemical irritants, or vital, as in the case of invading bacteria, the latter, of course, being frequently double in its action, both chemical and vital. This response to external irritation is of an active kind, and is manifested by actual movement towards, or away from, the irritant material. These two classes of movement are called positive chemiotaxis, and negative chemiotaxis, according as the movement is towards or away from the invaded part; and the property is manifestly an exceedingly powerful one, for it is seen to occur in all kinds of experiments and natural phenomena of the sort that would call it out, and is an occurrence familiar to every one who has ever seen a swelling in any of the vital tissues, the result of any sort of irritation.

From all the work that he and his followers have done in this direction, Metschnikoff reaches his well-known conclusions in regard to phagocytosis: that it is an active factor in the production of immunity from an infectious disease or in the recovery from such a disease; and that there is always an effort made in this direction, by such cells of the organism as may be possessed of this property of englobing and destroying bacteria.

The objections that have been raised to his conclusions are many, and have come very largely from German observers. Negative evidence in such a question may well be excluded; and an examination of the positive facts brought forward is exceedingly interesting.

Among the most active opponents of the assertions made by Metschnikoff was Christmas-Dirckinck-Holmfeld.[3] Defining his idea of Metschnikoff's idea of phagocytosis, he says that it is the ability of the leucocytes of various animals to "eat" (and thereby destroy) invading bacteria, and that immunity against infectious disease depends upon this ability of the leucocytes; that every organism is immune to all parasitic diseases, the parasites of which can be eaten by the phagocytes of the organism, whilst an organism cannot defend itself against any microparasite whose chemical or physiological properties are such that it cannot be destroyed by the leucocytes. This theory was at first received with enthusiasm until Baumgarten objected to it.[4] An answer to his objections being made by Metschnikoff,[5] Ribbert[6] made certain experiments with the aspergillus fumigatus and flavescens, by injections into the ear vein of rabbits. As a result, he saw a wall of leucocytes built about the spores (in the lung, the liver, and the spleen), by means of which their sprouting was circumscribed and was sometimes prevented entirely; and he concluded that the leucocytes prevented the development by suffocation, that is, by preventing the access of oxygen to the spores.

Wyssokowitsch[7] found that after the injection of non-pathogenic bacteria into the blood-vessels, some of them were taken up by the endothelial cells of the capillaries, but he could determine no activity of the white blood-corpuscles in taking up the bacteria, and therefore concluded that phagocytosis plays but a subordinate part in producing the harmlessness of bacteria. Such a conclusion at the present time, from such experiments, would certainly not be justified.

The special theoretical objections raised by Christmas-Dirckinck-Holmfeld are that Metschnikoff's experiments were made mostly upon cold-blooded animals kept at a temperature of 36°C., and that his experiments upon warm-blooded animals were very few; that it is true enough that in warm-blooded animals and in virulent diseases, like mouse-septicæmia and tuberculosis, there is manifest a tendency on the part of the cells to take up the bacteria, but it is also true that the bacteria of suppuration are almost never seen in the cells. He considers, also, that not enough attention was paid to the changes in the local site of the inoculation, and devoted his experiments to showing that these may be of the utmost importance. He used rabbits, mice and white rats for animals, and anthrax bacilli for material; the latter because Metschnikoff had done so, and also because they are easily seen, easily cultivated and characteristic. Rabbits and mice are very susceptible, whilst rats are very insusceptible — in fact, almost immune — to inoculations of these bacilli; so that all sorts of variation of effect may be seen by the use of these three kinds of animals. "The results show, constantly, a variation in the changes at the point of inoculation, in accordance with the greater or less susceptibility of the animal towards the material employed." Subcutaneous inoculation in mice and rabbits gave, twenty-four hours afterwards, a slight amount of clear serous exudation, that contained many anthrax rods, but no (or almost no) pus-corpuscles, and the number of these did not increase as time went on; there was only a local œdema, never any suppuration. With rats, on the other hand, the conditions found were different. In all these animals experimented upon, pus constantly occurred in the secretion from the wound, the amount varying with the virulence of the material used and the greater or less susceptibility

of the individual animal to the virus; the older the rat, the more marked the amount of pus.

Employment of attenuated virus gave a very different result, so far as rabbits and mice were concerned; in this case there always occurring a small localized suppuration.

The results of his inoculation experiments were, briefly, as follows: inoculation of anthrax bacilli of full virulence produced in very susceptible animals (rabbits and mice) a very slight (or almost no) reaction at the seat of the inoculation; suppuration *never* occurred; the inoculated bacteria quickly found their way throughout the organism by means of the lymph- and blood-channels, where they developed with great rapidity and produced the death of the animals. In slightly susceptible animals, the inoculated material produces a perceptible suppurative reaction in the tissues, and this pus-formation is in proportion to the greater or less susceptibility of the animals experimented upon; the less the susceptibility the greater the amount of pus-formation.

Pus-formation, therefore, plays no slight part in the determination of the greater or less susceptibility of animals towards anthrax; and not only in this disease, but the same thing is true of many of the infectious diseases. It is a common observation that the most virulent infectious diseases — those in which death occurs in a very short time (from hours to days) — are precisely those in which pus-formation does not occur; whilst those that are slow in action, in which fatal results occur late, if at all, are equally those in which marked pus-formation is seen.

This is perfectly true; but the facts may easily be interpreted in the line of believing that, where pus-formation does not occur, the phagocytic power of the body cells has been overcome by some influence upon their chemiotactic properties, rather than to make it a ground for rejecting recorded observations, or for relying upon the explanations of our author that follow. He considers that the means by which the bacteria are rendered harmless, are to be ascribed much more to chemico-biological action than to any power of the cells to absorb corpuscular elements, which is Metschnikoff's "anomalous supposition." He further states that by the observation of the behavior of the pus in insusceptible animals, it can be seen that the cells play no such part as is ascribed to them by Metschnikoff; for example, in the pus in rats inoculated with anthrax, and in animals in which the white corpuscles could with ease destroy the bacilli, very few of the bacteria are to be found in the cells; most of them are lying free in the fluids, and very few of them in the cells, whilst these show a slight tendency only to destroy the bacilli. The inoculation of attenuated anthrax-cultures in rabbits and mice shows the same thing — only rarely is there a rod in the cells; and in rabbits inoculated with cultures of full virulence, when pus-corpuscles are found at all, it is only here and there that a rod is to be seen in a cell; and the same is true of mice.

These results, the author claims, and with justice, are in sharp contrast to those of Metschnikoff, who, he says, used mostly warm-stage preparations from warm-blooded animals, with no observations in the living animals, most of his work being done upon cold-blooded animals, and therefore inapplicable to the warm-blooded races.

He gives other experiments, tending, as he thinks, to show that the bacilli are killed before phagocytosis can be supposed to have had time enough to take effect, and considers that the overcoming of these bacteria must be due either to the absence of oxygen or else to the production, during their development, of some material hurtful to their own existence.

(To be continued.)

CASES OF REMOVAL OF THE APPENDIX VERMIFORMIS BETWEEN ATTACKS OF RELAPSING INFLAMMATION.

BY A. T. CABOT, A.M., M.D.,
Surgeon to the Massachusetts General Hospital.

The contrast between an operation for the removal of the appendix vermiformis in an interval between attacks of inflammation, and the same operation done in the midst of an attack, is very striking.

When summoned to operate in the midst of an attack, the surgeon finds the patient usually exhausted by want of sleep and by pain. The field of operation is not aseptic, and the treatment previously directed against the inflammation with hot and stimulating fomentations, often of sufficient strength to cause blistering, has put the skin in a condition that makes asepsis impossible.

Then, the distention of the intestines, due partly to the inflammation, and partly to the opium which has been administered, interferes very decidedly with the operation. The tympanites, lifting the abdominal wall forward, increases the depth at which the appendix lies, so that it greatly adds to the difficulty of bringing it to the surface and removing it.

The presence of pus in these cases, too, adds a very serious complication. When the pus is shut up in a circumscribed cavity, the walls of which are composed of agglutinated coils of intestines, it may become impossible to properly separate and remove the appendix without liberating the pus among the healthy coils and infecting the general abdominal cavity. This condition may thus prevent the ideal completion of the operation by the removal of the appendix.

But suppose the operation completed. It is almost invariably necessary to establish drainage, and for this purpose to leave the wound in the abdomen but imperfectly closed. This imperfect closure of the wound leaves great liability to hernia.

After this picture of the difficulties which surround the operation done for an acute appendicitis, look at the condition which obtains when the operation is done in an interval of health between attacks. With thorough antiseptic precaution, the surgeon approaches the patient, who has been put in the best possible condition for the operation. His bowels have been emptied of their contents until the abdominal wall is flat and soft. His strength has been attended to, and he is in the best physical condition; his kidneys are acting well; his skin has been thoroughly prepared, so that there is no danger of contamination from the outside; and after the opening has been made, the appendix, though perhaps tied by adhesions and possibly so held by them as to be removed with difficulty, is, at least, not surrounded by pus, and the dissection necessary to free it can be carried out under the intelligent guidance of the eye.

The collapsed condition of the intestines gives the

operator room to work, and at the same time to shut off the rest of the peritoneal cavity with sponges during the manipulations. At the end of the operation, there being no necessity for drainage, the abdominal wound can be tightly and carefully sutured, so as to reduce the danger of any subsequent hernial protrusion to a minimum.

An operation done in an interval of health has, then, very great advantages over an operation done in the midst of an attack of inflammation. It would, therefore, seem wise, in cases of recurrent appendicitis (in which the attacks are sufficiently severe to make it seem probable that an emergency operation may be required in some of them), to accept the lesser risk and to do the operation when the patient is comparatively well. Especially is this the case when, owing to the patient's habits and inclinations, it is extremely irksome to have the danger of an attack hanging over him and interfering with his arrangements for business and pleasure.

It is impossible to lay down any rules by which the question, to operate or not to operate, shall be decided; but this judgment must be made in each case for itself.

The cases which I have operated upon and those which I have seen in the hands of other surgeons, have shown me that there is always a distinct reason for the tendency to recurrence of inflammation. In one of them it was found that, through the inflammatory action about the appendix, nature was effecting a cure of the condition. In the others, however, there did not seem to be any likelihood that the process was tending towards a cure. The following cases are reported as a contribution to the knowledge of the conditions which are likely to be found in these patients.

CASE I. The first operation of this sort that I did was on a young man of twenty-five, in November, 1890. It has already been reported at length, and I will only mention here the fact that I have recently heard of him as having been perfectly well since the operation.

The appendix in this case was strongly bent backward beneath the cæcum. It was somewhat enlarged, with thickened walls, which were infiltrated with round cells. The mucous membrane was destroyed by an extensive ulceration of its surface.

CASE II. Philip McD., twelve years old, was sent to the Massachusetts General Hospital, July 7, 1891, by Dr. Cowdrey, of Stoneham, with the following history:

In November, 1890, he had his first attack of severe abdominal pain. This was accompanied by vomiting and constipation. The pain was felt across the whole abdomen and lasted for three or four days. Since that time he had had twelve distinct attacks and many slight threatenings of an attack. At first there would be three or four weeks between the attacks, but latterly they had followed each other with intervals of ten days or less. The pain in the later attacks had always been distinctly localized in the right iliac region, and a tumor had been noticed in the right side. This tumor had not disappeared in the last two months, although it diminished in size between the attacks.

He was kept under observation for three or four weeks, and then, being in a quiescent state, he was operated upon.

An incision was made in the right linea semilunaris, and the tumor, which was then about the size of a mandarin orange, was found to be made up of omentum and coils of intestine bound together. These being separated and pulled aside, the end of the cæcum was found, and by following the tendinous line in its wall, the appendix was found to be sharply curled back beneath the caput coli and closely adherent in this position. Persistent attempts were made to separate it from its connection with the cæcum, but it was found impossible to do this without serious danger of extensive laceration of the bowel. It being thought that in its closely adherent condition, it was not likely to give subsequent trouble, and in the belief also that the attacks of pain might have been partly due to the adhesions in the region about, the operation was abandoned and the wound was closed by sutures.

The bowels moved on the second day, and the boy made an excellent recovery, going home at the end of the third week.

I subsequently heard from Dr. Cowdrey that he had one or two slight feelings of discomfort soon after he got home, and that since that time he has been perfectly well.

CASE III. Harry W. L., aged twenty-two, a machinist, entered the hospital October 19, 1892, with the object of having the appendix vermiformis removed in an interval between attacks of inflammation.

He had his first attack of pain in this region ten months and a half before entrance and since that time he has had eighteen attacks, which occurred about every two weeks when working, but when he was idle the intervals were lengthened to six or eight weeks. The earlier attacks did not keep him from his work. The pain was not very sharp at first, but it was distressing and gradually increased until it usually induced vomiting. The pain was always mainly localized in the right iliac region, but spread from there in many of the attacks over the abdomen, which then became much distended. The attacks usually passed off slowly and in the intervals between them he was perfectly well. The patient said that he could feel a lump in the region of the appendix just after each attack. He was a slender man of medium size.

Examination revealed but little in the region of the appendix. Deep pressure showed slight tenderness and there was a little mass to be felt about where the appendix might be expected. An examination of the urine showed the presence of a few hyaline and granular casts, with some blood and some epithelial cells adherent; due probably to a slight renal hyperæmia. He was kept quiet and treated with the liberal administration of water and with counter-irritants over the kidneys for a few days, when this condition of the urine gradually disappeared. While waiting for this, the patient had a slight attack of pain in the region of the appendix. Nothing could be felt during this attack, although it was severe enough to induce vomiting. There was no rise of temperature during it.

The patient finally being in good condition, the operation was done on October 26, 1892.

Incision was made in the usual place, the cæcum presented and the appendix was readily found. It was little, if at all, increased in size; the end of it was free, but at the middle it was tied down by a band of adhesions which bent it upon itself to a right angle. From this point to the cæcum there were many adhesions, but they yielded readily.

The meso-appendix having been separated, the ap-

pendix was tied close to the cæcum and then divided, a little cuff of the serous coat having been turned back before the division of the muscular and mucous coats. This cuff was then turned over the stump and stitched with one or two intestinal sutures.

After removal it was found that the appendix, which was somewhat thickened by chronic inflammation, contained a very small concretion. The wound was closed by silk sutures and the patient made a good recovery. He was out of bed on the twelfth day, and went home at the end of three weeks. Since that time he has remained perfectly well.

CASE IV. Frederic C. A., aged nineteen, a clerk, was sent to me by Dr. Cleaves, of Medford, in October, 1892, with the history that he had had two sharp attacks of appendicitis. The first of these attacks had occurred a year and a half before, and the last one had occurred in the previous April.

The first attack began with a very sharp pain in the front of the abdomen in the right iliac region. The pain gradually increased until the third day, when the patient took to his bed. There was tenderness in the region of the appendix, but no distention. Nausea, vomiting and diarrhœa accompanied the attack, and the bowels continued loose for a month. The pain was very severe and required the liberal use of morphine for its control. One week after the commencement of this attack a lump the size of an orange was noticed in the right iliac region, and this could also be felt through the rectum. As convalescence was established, this lump gradually and completely disappeared.

He was then well, except for occasional slight pain in that region, until the second attack. This was like the first, except that it only lasted one week and no tumor was discovered. The patient had been pretty well since this last attack, but insisted upon having the operation done, as he dreaded the possibility of another attack, and feared the chance of its occurring when medical aid was not easily to be had.

The examination of the abdomen was wholly negative. After consultation with Dr. R. H. Fitz, it was decided to accede to the patient's request, and the operation was performed November 1, 1892.

The incision was made in the usual place and the cæcum was readily found. The appendix extended directly down from it into the pelvis. It was very adherent and stretched far down into the pelvis, being continued by a broad adhesion from its end, which was apparently attached somewhere down near the rectum. It being found difficult to separate the appendix from this adhesion, the meso-appendix was tied off, and after the appendix had been ligatured close to the cæcum, it was cut away. It was now found possible, by traction, to separate the end of the organ from the adhesions in the pelvis, and it was removed. The wound was closed with silk sutures, after carefully cleansing the abdomen. The appendix contained a concretion about the size of a large bean.

On the second day it was found impossible to keep the patient quiet, he having no pain and moving about in bed readily. He was sitting up on the twelfth day, and was discharged at the end of three weeks. December 21st, having been on a vacation, he wrote that he was feeling finely — "In fact," he said, "I don't believe I ever felt better."

CASE V. Philip C., twenty-one years of age, applied to me in January, 1893, for the removal of the appendix vermiformis. He had had five attacks of appendicitis, the first in March, 1889, when he was in bed for two weeks and had a tumor in the ileo-cæcal region. In May of the same year he had a similar attack, but more severe with a larger tumor. This time he was sick for three months, and Dr. G. K. Sabine, who attended him, thought there was suppuration about the appendix. The next attack came in October, 1892, lasting three weeks and followed by another soon after, lasting two weeks. On December 17, 1892, he had the last attack before he entered the hospital, which also lasted two weeks. In these attacks there was a distinct tumor to be felt.

The operation was done January 11, 1893. The incision was made in the usual place, about two inches long. The appendix was readily found, but was very adherent to the omentum and was twisted upon itself and adherent to its own mesentery. The adhesions were freed with the finger; but in separating the omentum from the angle made by the sharp bend in the appendix, a tear was made from which a few drops of pus oozed out. The appendix was readily separated from its mesentery and drawn out. After a cuff of the serous coat had been turned back, a ligature was tied around the muscular and mucous coats, and the appendix was cut off. The cuff of the serous coat was then stitched over the stump.

The patient made a good recovery from this operation, somewhat retarded, however, by suppuration of the outer part of the wound. It seems probable that this became contaminated at the time that pus escaped from the appendix, as the most thorough precautions were taken in every other respect to protect the wound from infection. I saw him last about February 15th, and at that time the wound was thoroughly healed, and he was having no discomfort of any kind.

Dr. Whitney describes this appendix as being constricted in the middle and bent upon itself. Its lumen was not obliterated at the point of constriction, as a fine bristle could be passed through it.

Microscopic examination of the constricted portion showed the glandular layers considerably destroyed, irregular and infiltrated with round cells, which could also be followed out into the muscular coats. Adherent to the tip of the appendix was a small, firm mass, which showed a muscular coat encircling it, but a lumen entirely filled up with connective and fat tissue. It seems probable that this was a portion of the tip which had become obliterated and constricted entirely off from the rest. The tissues about the base of the appendix were quite normal.

It is noticeable that in all but one of these cases, the appendix was sharply bent upon itself. In one, at least, there was a very decided narrowing of the lumen at the angle. The bend was so sharp in each of them that it caused a constriction at that point, and I am inclined to regard the constriction of the lumen of the appendix as in great measure responsible for the recurring attacks of inflammation.

When an appendix which is congenitally bent upon itself and thus narrowed, or which has become so by an attack of inflammation, is affected by a catarrhal process, the fluid secreted in the distal portion cannot readily find its way back and discharge into the bowel. This leads to the distention of the part shut off. If the pressure finally overcomes the resistance at the point of occlusion, the fluid escapes into the intestine, and the pain caused by the stretching of the wall of the appendix ceases. This course of things would ac-

count for the frequently-repeated, mild attacks seen in some of these cases.

After this was written I saw the following case, which seems to illustrate this point, and in which the reported observations have been carefully made; the patient being himself a physician with a lax abdomen, in which careful and accurate palpation could be obtained.

He is thirty-three years old, and has for six or seven years been subject to attacks in the right lower segment of the abdomen. They have been variable in frequency, sometimes being but three or four weeks apart, and again there being a period of six or seven months without one.

There is apt to be a little premonitory discomfort in the abdomen; but when the sharp attack comes, the pain is agonizing, and sometimes accompanied by vomiting. The severe pain usually lasts from one and a half to three hours.

He has made careful examinations of the cæcal regions during these attacks, and his observations have been confirmed by other good observers.

Early in an attack the appendix may be felt as a distinct tumor which is not especially sensitive. The pain is at first paroxysmal in character; later the paroxysms often run together in such a way that the pain is constant, with occasional exacerbations. During the course of the attack, the region of the appendix becomes more and more sensitive to pressure. The appendix may be felt contracting "like a uterus" during a paroxysm.

A constant phenomenon is the final, sudden cessation of pain immediately following the only retching or vomiting of the attack. There has never been any disturbance of urination, or any after trouble in the bowels.

The pain during the attack is referred to the abdomen in general, more in the region of the umbilicus. It is not localized in the cæcal region. After its sudden cessation there is left a little local tenderness, a sense of stiffness, especially in walking, and a small tumor in the region of the appendix, all of which symptoms pass off in twenty-four or forty-eight hours.

This seems to be distinctly the history of an accumulation of fluid in the appendix causing pain by distention; which pain is finally relieved by the escape of the fluid into the bowel. If the occlusion is so complete that the fluid cannot escape, it may be absorbed, or it may break through the wall into the peritoneal cavity.

I have at autopsy seen one case in which an appendix which showed little evidence of inflammation, but which had in a previous attack been occluded, had ruptured and discharged its contents, setting up a general peritonitis. Although the escaped material usually sets up a severe peritonitis, in some cases it is probable that the peritoneum is able to absorb and so dispose of an effusion of this sort. In the fifth case that I have reported, there can be but little doubt that the appendix had been previously ruptured; for the gentle separation of the omentum at once revealed an opening beneath it.

The occurrence of a large tumor in this case in one of the early attacks, points to the probable existence of an abscess at that time. Its subsequent disappearance was due either to the absorption of the pus, or to its gradual discharge through the perforated appendix or into the bowel at some other point.

The fourth case is interesting as being the only one in which a considerable concretion was found; and in spite of the presence of this foreign body, there had been no attack of pain for seven months.

It is possible, and I think probable, that the position of the appendix accounts for this immunity from pain. It was adherent in such a way that it was held stretched in a straight line, and as its lumen was not obstructed, the fluids forming in it had an easy road of escape into the bowel.

My remarks upon the advantages of an operation done between attacks over an operation done after the formation of pus and adhesions, may be applied with modified force to the operation in the midst of an attack, and the considerations urged there clearly set forth the importance of operating early, when the attack is of such severity as to indicate the probable necessity of interference. I find that I am more and more inclined to immediate operation when the presence of a sharp attack of appendicular inflammation is established; but I still see occasional cases in which the inflammation is of so mild a grade as to make it seem wise to wait the subsidence of the attack, with the intention, if it is repeated, of operating in some interval of health.

One consideration which has sometimes led me to delay operation, has been the difficulty of accomplishing a thoroughly antiseptic operation in the surroundings in which we often find these patients; and with the object of making this occasional objection more rare, I wish to suggest to general practitioners that it would be wise, *in the presence of abdominal symptoms pointing to the possible necessity for surgical intervention, to always apply antiseptic fomentations, so that when the surgeon is called, he shall find an aseptic field of operation.*

Since this paper was read, an interesting article has been published upon this subject by Dr. William T. Bull, in the New York *Medical Record* for March 18, 1893. In Dr. Bull's cases he found, as I did, that there was generally some malposition of the appendix, which tended to reproduce the attacks. This was usually either a sharp bend, or a constriction in the appendix.

He has collected seventy-six published cases, with one death. In his collection of cases he includes my first case, which had been previously reported. Adding to these my other four cases brings the number up to eighty with but one death.[1]

It is to be feared that these statistics may be, in a measure, selected cases as successful cases are likely to be reported, while those that turned out unfavorably may not have been yet published. Even allowing something on this score, these results are certainly very encouraging. If a surgeon by the operation can offer a risk of but one and a half per cent., he may, I think, consider this a better chance than that which the patient would take if not operated upon.

Within a couple of months I have seen a man who had had two mild attacks, and who finally had a severe attack, of which he died, although the operation was done as soon as he was seen, at the end of the second day. The condition found was a sloughing appendix and a general purulent peritonitis. This is one example of many, in which mild attacks have finally led up to a severe and dangerous one.

[1] Since this paper was in press I have operated on two more of these cases and they have made good recoveries. In both, the appendix was sharply bent, and fastened in that position by adhesions.

New Instruments.

A SIMPLE SUBSTITUTE FOR THE LEITER COIL.

BY FRANK B. SPRAGUE, M.D., PROVIDENCE, R. I.,
Assistant Surgeon to the Ear, Nose and Throat Department, Rhode Island Hospital.

THE accompanying cut illustrates a rubber bag made for the purpose of applying cold or heat to the mastoid region. A clamp (not shown in the cut) securely closes the neck, making it water-tight. It is applied with the wide part over the mastoid, the clamped end uppermost, and the auricle protruding through the opening. A piece of tape, fastened in the rings above and below and passing under the chin and over the head, where it is tied, holds it in place securely; fastened in this way, it may be worn while the patient is sitting up or in the recumbent posture, and by reversing the clamp it may be worn on either side.

This simple apparatus is a good substitute for the Leiter Coil, and is more convenient for many cases in private practice. When filled with cracked ice it will serve its purpose for about an hour, being therefore much more convenient than the cold compresses commonly used, which require changing every two or three minutes, and entail a wetting of the skin, which is liable to excoriate it and add to the discomfort of the patient. It can also be used as a hot-water bag if desired.

NOTE — The bag is manufactured by the Davol Rubber Company of Providence, R. I., and can be obtained of dealers in surgical appliances at a nominal price, within the reach of a dispensary patient.

Medical Progress.

RECENT PROGRESS IN FOODS, DRUGS AND ARTICLES OF DOMESTIC USE.

BY B. F. DAVENPORT, M.D.

THE CHEMICAL DIFFERENCE IN COMPOSITION BETWEEN COW AND HUMAN MILK, AND THE MEANS FOR CORRECTING THEM.[1]

IN his paper before the Medical Society of Munich, upon a better method of sterilizing milk, Professor Soxhlet has pointed out that although this would remove the more important difference, yet it did not give to cow's milk all the properties which the natural food of the infant possesses. There still remains differences of a chemical nature which should also be removed.

Of those differences the following are the more important: (1) the different manner in which their caseins coagulated; (2) their different proportions of lime-salts; (3) the difference in their absolute amount of nutriment, and in the proportion of the separate ingredients to each other.

[1] By Prof. Dr. F. Soxhlet, Münchener Med. Wochenschrift, January 24, 1893.

The first of the above differences has hitherto been considered of the greatest practical importance, because the less easy digestibility of the cow casein has been ascribed to its manner of coagulation; for cow's milk, when either acid or rennet has been added, produces a firmer curd than does human milk. We, however, now know that its manner of acting with rennet is alone of importance in this regard, and as this is quite a different process for its action with acids, all the conclusions hitherto based upon its action with muriatic acid or with this acid and pepsin are without any real significance as to its use as an infant food.

The difference in the manner of coagulation is not a sufficient ground for inferring a chemical difference in the caseins themselves. The firmness of the curd produced by the rennet of the stomach depends entirely upon the concentration of the casein solution, the amount of soluble lime-salts present, and upon the acidity of the solution.

With cow's milk all three of the above conditions are strongly unfavorable for its manner of coagulating. For cow's milk contains about twice as much casein, six times as much lime, and about three times as great acidity as does human milk. No wonder that with such a composition its coagulum is leathery, while the other is fine and flocculent. By proper dilution with water and neutralization, however, can cow's milk be so altered as to coagulate very much like human milk; yet it cannot be made to act exactly like it, because that the amount of lime-salts present cannot be lessened. The dilution with water has long been used as a practical means of lessening their differences. The addition of alkalies to reduce the acidity to that of human milk has been a second practical method. But a cow's milk so neutralized cannot be sterilized without suffering a marked alteration, for the milk-sugar being acted upon, the milk becomes brown and acquires a burnt flavor. Human milk would undergo a like change if sterilized, even without any addition. In neutralizing the cow's milk, therefore, it must be done after the sterilization, and best just before using by adding to each 100 grammes (or about three fluid ounces) 0.1 gramme (1.5 grains) of bicarbonate of soda, which may be in the form of a lozenge such as is prepared by apothecaries. This correction of the acidity is useful whenever a particularly firm curd is formed or the stomach secretes a larger amount of acid or of lime-salt than usual; otherwise every complication or opportunity for a renewed infection of the milk had better be avoided.

The more the milk is diluted with water the more flocculent becomes the curd which is formed. But this addition is limited by other conditions which are as important for nutrition as fineness of the curd. By too much dilution the volume of food to be taken becomes either excessive, or the absolute quantity taken too little for a satisfactory growth. An increased consumption of water increases the waste of albumin and of fat, and hinders the growth of the body. Furthermore, the increased excretion of urine disturbs the child and interferes with its well being. The chief disadvantage of too much dilution lies plainly in too little supply of nourishment, as a simple calculation shows. According to the investigation of E. Pfeiffer, a nursling of eight to nine weeks in age consumes daily 900 grms. of breast milk, a bottle-fed child given a like quantity of a mixture of one part cow's milk with three parts of water would receive but 8 grms. of

albumin while the breast-fed child had 20.6 grms. Of total nutriment, the child at the breast would receive 113 grms., while the artificially-fed child only 29 grms. The latter, upon the base of albumin consumed, would be receiving not 900, but only 350 grms. of breast milk, while upon the base of total nutriment, the equivalent of only 230 grms. of breast milk. To satisfy its needs, it must, in place of the 900 grms. of breast milk, consume of the threefold diluted cow's milk 2,250 grms. for the albumin, or 3,600 grms. for the total solids. Such a disproportion of nutriment is a crying evil. Water, by ever so careful a sterilization, will never become breast milk. It will increase the number of the wet diapers but not the weight of the body.

Milk which has been boiled gives a very finely flocculent curd with rennet, and requires much more of the ferment. This alteration is in proportion to the duration and the high degree of the heating. It would be erroneous, however, to infer therefrom a more easy digestibility of boiled or sterilized milk, or indeed to assert the opposite, as some have done. Within the stomach boiled milk is reconverted to the condition of an unboiled milk as regards its relation to rennet. Through the heating, the soluble lime-salts which are necessary for the action of the rennet, are rendered insoluble. But in the stomach, by the entrance of a small quantity of acid, or more probably of soluble lime-salts there secreted, the original proportion of soluble lime-salts is restored or even a little increased. Boiled milk will therefore often coagulate into a firmer curd within the stomach than the unboiled milk would out of it. In artificial experiments upon digestion without the stomach this regeneration of boiled milk must be taken into consideration, not to be led into such wrong conclusions as have already been drawn. Additions of mucilaginous fluids, as barley water, oatmeal decoction, or of arrowroot or other starches, calves'-foot broth, etc., have no other influence upon the curdling of milk by rennet than so much water. The conclusions of the favorable influence of such additions upon curdling were based upon experiments with acids, and not upon actual curdling experiments in the stomach of nurslings. As to the nutrient value of such decoctions, erroneous conclusions are easily drawn from their substantial appearance. As a rule, however, they are only about one per cent. mucilage of starch, a fluid very poor in nutriment. Such fluids may, nevertheless, be useful in many cases, although their hitherto considered cause may be erroneous.

The confounding of substantial appearance and nutrient value has played an important rôle in estimating the nutrient value of children's foods, which in spite of roasting and baking still contain starch but a little altered, and which, therefore, although boiled with much water, still form a thick mass. If one adds a little active malt-extract to such a food while warm, it is changed into a thin broth, which in spite of its thinner appearance is of increased nutrient value, for the starch paste has been changed into sugar. Such preparations have proved useful in that they have had to be freshly made and boiled for each meal. This indirect advantage, however, has now been more completely and with less trouble reached through sterilization.

The difference between cow and breast milk in regard to mineral constituents is principally that the former contains two to three times as much; that it has four times as much phosphoric acid, and six times as much lime as breast milk. It has also a notable excess of phosphate of lime over that needed for the growth of the bones. This is not used, but is thrown off in the fæces in the form of an excess of lime soap. In both kinds of milk the dissolved lime, which plays such an important part in the coagulation of milk, exists principally in the form of citrate of lime. Any increase of lime-salts in a milk is not only useless but harmful, in so far as it increases the firmness of the coagulation. Soda or potash alkaline salts act in the opposite way.

The most important difference between the two kinds of milk lies in their different amounts of nutrient substance, and the varying proportions of the single ingredients; for the effect produced by foods depends essentially upon the absolute quantity of the material supplied and upon the proportions they bear to each other. When there is so great a difference in both respects as between cow and breast milk a different nutrient action is to be expected. These grosser differences need removal before the lesser ones are attended to. According to J. Konig, upon the average of the analysis of 793 cow and of 107 breast milks, the following percentages were obtained:

	Water.	Albu'ds.	Fat.	Sugar.	Ash.
Breast milk	87.41	2.29	3.78	6.21	0.31
Cow milk	87.17	3.55	3.69	4.88	0.71
Cow milk excess	..	1.26	..	..	0.40
Cow milk deficit	0.24	..	0.09	1.33	..

According to the analyses as given in Hammarsten's "Physiologische Chemie," breast milk contains upon the average 2.01 per cent. of albuminoids, 3.52 fat, 5.91 sugar. By diluting cow's milk with half its volume of a six-per-cent. solution of milk-sugar, a mixture is obtained which contains just as much albuminoids and sugar, but about 1.32 per cent. less fat than breast milk. It then becomes a question how to attain the normal fat percentage of breast milk. Biedert has recommended the use of cream in place of milk; while Soxhlet had in 1886 recommended the strippings of the milking to avoid a strongly infected cream. Both of these methods present great difficulties. Especially are means for estimating the percentage of fat wanting. In the mixed milk of normally-fed cows we possess a food of a constant and well-known composition. We know how much nutriment is furnished by such a milk; in the other cases we loose this advantage. Furthermore, an over-rich milk cannot be sterilized without the fat globules running together and breaking up the emulsion, which is so important in the absorption of the fat. Upon practical grounds, therefore, we must choose the less correct but safer rule of making up the deficient one-third fat by the addition of another substance as nearly equivalent to it as possible. The fat of food acts in the body as an economizer of albumin, it yields heat or energy and is assimulated as fat into the body. All these functions, the carbohydrate already present, the milk-sugar, can also accomplish, according to the experiments of Rubner 243 parts of milk-sugar are equal in dynamic energy to 100 parts of fat. The 1.32 per cent. of fat wanting in the milk mixture can therefore be supplied by 3.19 per cent. of milk-sugar.

By adding to cow's milk, therefore, half its volume of a 12.3 per cent. solution of milk-sugar, one would obtain a mixture containing the same amount of nutrient materials as breast-milk, with only the slight

change of one-third of the fat being replaced by its equivalent in milk-sugar:

	Breast Milk.	Cow's Milk, with a half-volume of 12.3% sol. of milk-sugar.
Water,	87.41%	85.30%
Albuminoids,	2.29	2.37
Fat,	3.78	2.46
Fat replaced by sugar,	..	1.32
Sugar equivalent,	..	3.19
Sugar, natural,	6.21	3.25
Sugar, natural deficit,	..	2.96
Total sugar,	..	9.40
Ash.	0.31	0.47

It still remains to be considered whether milk-sugar is really the only rational addition for the milk, or whether this may not be replaced by another, possibly a still better or at least a cheaper substance.

The milk of all animals contains no other carbohydrate than milk-sugar along with small quantities of similar substances. It is not in their blood, but is a product of the milk gland. Further than in the milk (and in cases of over-accumulation in the urine also) milk-sugar is found nowhere else either in the animal or vegetable kingdom. It is the only carbohydrate on which the young of all mammals are fed. This is so marked an indication of the best source from which material is to be obtained for making up the deficiency in cow's milk, that it would be useless and superfluous to seek for anything better. That starch is a most unsuitable substitute for milk-sugar there cannot longer be any doubt. As regards the soluble products of the conversion of starch, dextrin and the sugars, the former is chemically and physiologically much further removed from milk-sugar than either cane, grape-sugar or maltose.

Adults who live upon mixed food consume starch as their principal carbohydrate. It is changed by the digestive ferments mostly into maltose, and in a less degree into dextrin. Indirectly maltose is the principal nutriment of most adults. Since nurslings possess only in a very slight degree the ability of converting starch into sugar, one could relieve them of this labor, and convert the starch through a malt-extract into maltose and dextrin, thus furnishing them the normal carbohydrate of adults in a form ready for direct absorption. This has in fact been done in Liebig's broth which is a wheat-flour converted by malt-extract, and in similar preparations, which have served a good purpose as additions to cow's milk.

Nevertheless, there are still so important differences between milk-sugar and the other sugars that one can regard neither maltose, cane or grape sugar as a complete substitute for milk-sugar. It is not only in regard to the natural occurrence of milk-sugar and its characteristics, that it is peculiar, but also because of its very peculiar behavior in the organism, that milk-sugar occupies an exceptionable position in the sugar group. Attention has not hitherto been directed to this point, although milk-sugar has frequently been suggested as an addition to cow's milk. The imitation of nature, a procedure which in similar instances is certain not to fail and has not hitherto been sufficiently insisted upon, for milk-sugar has been comparatively little used in the practice of infant feeding, while the most unnatural additions, such as preparations of starch and other kinds of farinaceous food, have occupied the chief place. It will be useful, therefore, to particularize the most important chemical and physiological differences between milk-sugar and the other sugars, so as to establish the indispensability of milk-sugar for the purpose, and to show that the exclusive indication of this carbohydrate as a natural food for infants is a well-founded adaptation.

(1) Milk-sugar, with raffinose (which does not here come into consideration), is the only sugar, which, by heating with nitric acid, produces mucic acid. The other sugars produce saccharic acid.

(2) Cane, grape sugar and maltose are converted, by ordinary alcoholic ferment, into alcohol and carbonic acid; milk-sugar remains unaltered. Milk-sugar is in general, more resistant to fermentative changes.

(3) It is only one-third as sweet as cane sugar, so one can add three times as much before inducing an unpleasant sweetness. In proportion to its action as a sweetener, it has more the character of a food, so that it can be also put to other food purposes in so far as its strong laxative action does not hinder.

(4) According to the investigations of Lusk, Abbot and Otto, milk-sugar is not changed like grape, cane and fruit sugar or maltose into glykogen. Hence, Voit infers from its action with diabetics, that it is more easily oxidized in the organism than other sugars. According to Bischoff and others, it passes most readily into the urine, because, according to Voit, it is not converted directly into glykogen and thus removed from the circulation.

The following particulars, drawn from the investigation of P. Albertoni, first published within two years, are of special interest in regard to the exceptional position of milk-sugar to the organism.

(5) Maltose and cane sugar are the most quickly absorbed, milk-sugar the slowest; of the former, 70 to 80 per cent. within an hour, of the latter, 20 to 40 per cent., according to the concentration, are absorbed.

(6) The accumulation of the quickly absorbable sugars, cane, grape and maltose, in the blood, induces changes in the functions of the circulatory apparatus which lasts until the excess of sugar disappears. The blood pressure rises, the vessels expand, and the pulse beat increases. The circulation is so much increased that it is doubled. Milk-sugar also exerts a peculiar influence. It increases the blood pressure, but not the frequency of the pulse. It even reduces it, but the systole becomes more extended. The increase of the pressure depends upon the direct excitant action of the sugar upon the heart and its vessels, while the slowing of the pulse depends upon the specific action of the milk-sugar upon the heart. Albertoni regards the sugars, not only as foods and condiments in their usual sense, but also as specific excitants for regulating the circulation. It is from this point of view, not indifferent whether milk-sugar be replaced by other sugars, for on account of its slower absorption and easier oxidation, it does not so easily accumulate in the blood, and furthermore, its exciting action is different and peculiar.

(7) While other sugars are quite completely absorbed from the stomach, a large proportion of the milk-sugar consumed is always to be found in the small intestines. Some while after the taking of a milk-sugar solution the stomach and intestines together will always contain more fluid than was taken, and the small intestines will contain more mucus and bile than usual. This explains the laxative action of milk-sugar and it is used for this purpose. The laxative action which milk has upon many is to be ascribed to the sugar. Traube prescribes it in doses of nine to sixteen grammes to be taken before breakfast in half a litre of warm

milk. Albertoni commends it in doses of twenty grammes. This specific action of the sugar renders it a particularly valuable adjunct to cow's milk. The frequently solid consistency of the fæces of bottle-fed infants is certainly due to the small amount of milk-sugar in their food, and probably the indigestibility of cow's milk casein may be due to the same cause. It must, however, be remembered that the laxative action of milk-sugar depends not only upon the quantity, but also upon the concentration of the solution; and much diluted solutions, like much diluted cow's milk, will not have this action.

(8) Of especial interest are, finally, the recent investigations of Albertoni concerning the so-called chemotactic action of milk-sugar. W. Pfeiffer has shown that many organisms endowed with locomotion, as bacteria, flagellatæ, volvocineæ, fern spores, etc., are attracted or repelled through the exciting action of certain materials. If one fills a capillary tube, closed at one end, with a strongly attracting substance, such as a one-hundredth-per-cent. solution of peptone or of meat extract, and immerses it in water containing such organisms as have been named, they will hasten to its mouth and collect within the tube. White blood-corpuscles will act in like manner and swim into a capillary tube, which, filled with an attracting substance, is introduced under the skin. Professor Buchner has shown that bacterial protein, vegetable casein and albuminates are the strongest chemical excitants for leucocytes. In like manner Albertoni has investigated the exciting action of the various kinds of sugar upon the white blood-corpuscles, by inserting capillary tubes filled with a five-per-cent. solution of the sugar under the skin of animals, and after twenty-four hours staying, examining their contents. In kittens he found that with grape-sugar the white blood-corpuscles were excited, with cane-sugar they were but little, while with milk-sugar they were unusually excitable. Although Albertoni in giving his opinion as to the significance of the chemotactic action of the white blood-corpuscles suggests that such susceptibility to attraction facilitates the transport of digested and metamorphosed material to the anatomical elements of the tissues, just as the red corpuscles transport oxygen to them. It must also be remembered that, according to Pfeiffer's observation, this attractive influence does not always indicate natural adaptation, for poisons act as attractive materials, while other good nutritive material, as glycerine, exercises no excitant action. So much, however, is certain that milk-sugar exerts a very strong excitant action upon the leucocytes of the newly-born, while cane-sugar has no such action at all. So striking is this difference that it is scarcely possible to regard it as destitute of significance. In any case, this behavior of milk-sugar is calculated to mark very distinctly the physiological position which milk-sugar occupies among the sugars. Furthermore, Pfeiffer has already remarked the much stronger chemical exciting action of milk-sugar in that he has shown that a one-per-cent. solution of milk-sugar had as strong an attraction for bacterium termo as a ten-per-cent. solution of grape-sugar.

DR. ERNEST HART, on his return to England said: "It is idle and foolish for any British doctor who has time and the moderate means at command, to think of spending his autumn elsewhere than in America."

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

Regular meeting, Monday, April 10, 1893, the President, DR. C. F. FOLSOM, in the chair.

DR. H. C. ERNST read a paper on

PHAGOCYTOSIS,[1]

which was illustrated by lantern slides.

DR. R. H. FITZ: I hardly feel able to enter into a discussion of Dr. Ernst's paper. I have listened with great interest, and I think we all ought to congratulate him on the fairness with which he has stated the theory. I was somewhat interested when he said that the objections which were being raised to the theory emanated largely from Germany. I do not think that statement should pass without question. Certainly some of those working in behalf of the theory were Germans. When I was in Germany two years ago, several of the Germans with whom I talked in regard to the matter were very definitely of the opinion that there was a good deal in the theory, and that, practically, is, as I understand, the position at the present time. Certainly so far as it represents a theory it seems to give a very satisfactory explanation to a considerable number of facts that occur, and the illustrations Dr. Ernst has given us are striking instances of the relations between the cells and organisms. The phagocytic action is not necessarily applied to all bacteria, but there are certain bacteria which seem especially under the influence of this action. So far as protection is concerned, I remember as a student hearing the statement that there was no better protection to a wound than a pus poultice, and this phagocytic action of the cells as shown to us to-night seems to be an illustration in modern scientific method of what was then a popular belief.

A point which suggested itself to me in connection with Dr. Ernst's statement of the theory was, it might be that certain diseases were not so bad after all, at all events in certain directions. We are all inclined to look upon the disease leukæmia as a very serious affection. It distinctly is, but from the protective theory of phagocytic action it would seem the more white corpuscles a person had in him the better he would be able to resist certain bacterial influences and it is possible that investigations in this direction may show that the leukæmic individual is much less likely to suffer from certain diseases than one who has fewer white corpuscles.

DR. H. JACKSON: We have all been much interested in hearing this explanation of the Metschnikoff theory, and as Dr. Ernst says, an immense amount of work has been done, perhaps notably by the Germans, manifestly opposing the theory as promulgated by Metschnikoff. Of course, the German school who find in the blood-serum some anti-bacterial agent, do not consider phagocytosis as an important element in the destruction of bacteria. The earliest work was, I think, a paper by Nuttall, who repeated Metschnikoff's experiments with the frog, and drew the conclusion, from a very long series of experiments, that there was something in the blood-serum and other fluids of the body which possessed anti-bacterial prop-

[1] See page 85 of the Journal.

erties other than was present or could be explained by phagocytes. Later experimenters have extracted from blood-serum and from other fluids of the body a chemical product, not yet a pure chemical product, but a product obtained from blood-serum by precipitation, which apparently possesses the properties of the blood-serum. As Dr. Ernst says, a large amount of negative evidence is of no great value, and as Metschnikoff says that we cannot deny the existence of a process because we have never seen it, so we may draw arguments against the theory of Metschnikoff from the few positive pathological phenomena which are observed, namely, the relation of bacteria to the cells in certain well-known diseases. In diphtheria, for instance, when it has been produced by inoculation in guinea pigs, there is found a serous, jelly-like exudation at the point of the inoculation. There are found a large number of the bacilli of diphtheria in the leucocytes, but the leucocytes are, as far as we can judge from pathological study, dead and not living. Their cell protoplasm is broken up. The nuclei are not stained with clearness as in living fresh cells, so that it seems that we must draw the conclusion that the bacilli are destroying the cells rather than that the cells are destroying the bacilli. The commonest instance which comes under the observation of all who work at all in bacteriology, is the relation of the organism of gonorrhœa to the cells. In this disease the micro-organisms are found essentially in the cells. In examining a specimen you find a very large number of cases where there is only left a very slight outline of what was apparently a cell. Such an outline may be traced by staining reagents. Again, masses of the gonococci are found in such relation to one another that it appears most probable that they represent a small area which was originally a cell, that the cell has disappeared, and on the other hand the micro-organisms themselves, so far from showing any evidence of degeneration, are apparently in their most active growth.

As to the conclusions which we can draw from the diagrams which have been thrown upon the board, in a certain number of the pictures shown by Dr. Ernst, the bacteria were rather pale, and in some instances broken up as if they had been destroyed by the cell. In many pictures we could trace the nuclei perhaps on the edge of the cell, but at least a third, and in many instances two-thirds of the outline of the cell had disappeared. These were not micro-photographs, but taken from camera lucida drawings, that is, the observer could trace only the bits of nuclei, a large number of bacteria in close relation to the nuclei and a portion of a formerly whole cell membrane. In one of the diagrams which Dr. Ernst threw upon the board was a macrophagocyte taken from the eye of a pigeon, in which the microphagocyte was represented by a small round body and protruding through it was a long thread-like body, showing that the bacillus in the cell was not dead, but had multiplied until a long thread of bacilli was formed. In that instance the macrophagocyte had not destroyed the bacillus. Also one of the pictures represented what Dr. Ernst said was a dead macrophagocyte being carried about by the bacilli. In that instance the macrophagocyte had been overpowered by the bacilli, and not the bacilli by the macrophagocyte.

DR. A. K. STONE: I think we have all got a very clear idea of the subject that has been presented to us to-night, and that Dr. Ernst has given us very faithfully and carefully the theory of Metschnikoff. It is perhaps well to think that the work of Metschnikoff as it started out is the one which has brought about all the work that has since been done in the blood-serum therapy. The work in regard to blood-serum was undertaken by the men who followed up the work done on the theory propounded by Metschnikoff, and I should take exception to what Dr. Ernst said that it was confined to the German school. Certainly there are extremely good men in France and Italy, and also even in Japan, who are contributing work in this other line, so that I do not think it is fair to say that it is simply the German school that is opposing it, and much of this work is accepted, especially the Italian work, and is quoted by Metschnikoff himself in his book on inflammation, as being work that he accepts and considers as faithful work, in which he could not find any flaw. Almost all the Germans, even those who strongly opposed his theory, state very decidedly that there is a certain amount to the theory and that the phagocytes do play a limited rôle protecting against and taking up the bacteria, but consider that it is of minor importance. There are some arguments showing that only a small part is played by the phagocytes. One is that injection of ptomaines into an animal where there were absolutely no bacteria present, only the toxic products that have been made during their growth, is able to kill the animal without any active phagocytosis. Another fact is that bacteria may be present in great numbers and produce most unfavorable results without bringing about phagocytosis, so that neither chemically nor mechanically is it necessary that the phagocyte be present. Then from analogy we know that all the processes of the body that go for its nourishment and for the removal of waste material from the body for cleansing it, are the result of most complicated chemical reactions, and this would hint that the probability is that the inflammatory process is primarily way down at bottom a chemical process rather than the simple action of the cells themselves.

DR. ERNST: The remark I made about the German school seems to have been misunderstood. I did not mean to say they were the only ones that opposed the theory. Dr. Jackson quotes gonorrhœa and the appearances upon certain slides as indicating that certain of the bacteria do overcome the phagocytes; a condition of things that of course has nothing whatever to do with phagocytosis, because it would be absurd to suppose that any class of phagocytes could invariably and always overcome the bacteria.

ANATOMICAL SPECIMENS.

DR. WALTON: This is a cerebral tumor from a patient of Dr. Hooker, of Springfield, who called me in consultation February 22, 1892. The patient had had intense headache, vomiting and recurring aphasia, with paralysis of the sixth nerve on the left. When I saw him he had some aphasia, word-blindness, and word-deafness at times. He also had loss of vision on one side of both eyes (hemianopsia). This gives us a very good opportunity to study the localization of tumors outside the motor tract. This did not involve the motor tract either directly or indirectly. The mind-blindness pointed to disturbance in the angular gyrus. Word-deafness would show lesion in the posterior part of the first temporal lobe. Aphasia would

show some disturbance either in the island of Reil or at the lower end of the ascending frontal convolution. Paralysis of the sixth nerve would point to disturbance at the base of the brain, but as there was no other basal paralysis, we concluded that the sixth was affected by general pressure. As the aphasia was transitory, it seemed that it would hardly do to locate the tumor at the centre of speech, especially in the absence of facial paralysis. We did have one fixed and continuous symptom, namely, loss of vision affecting the left half of the retina. This might tend to show pressure on the optic tract somewhere, but might also show a lesion of the occipital region or of the fibres passing from the occipital region. What made us think it was near the cortex in this region was the fact that the patient often saw red spots. We concluded that the angular gyrus was affected directly, perhaps also the occipital lobe. Large doses of iodide were first used, with no effect. Five weeks later Dr. Richardson operated. We found the tumor was too deep and large for removal. It is a more or less lobulated mass starting deep down, probably from the fovea centralis. Its seat was practically where we located it. It had pressed the tissues forward so that the fissure of Sylvius is quite vertical instead of horizontal. The posterior part of the temporal region was affected, also the angular gyrus. The occipital region is separated from the temporal by the tumor, which extends nearly to the mesial surface of the brain, cutting off the fibres radiating to the occipital lobe. The patient lived two months, with temporary relief of pressure symptoms including the sixth nerve paralysis.

DR. RICHARDSON: There was nothing unusual in the operation. When the bone had been removed no pulsation could be detected. The dura mater was freely incised and turned back. The brain in appearance was not normal, but there was no evidence of the distinctly outlined tumor that can be seen now. With rongeur forceps I extended the cut in the skull, and enlarged the opening in the dura mater. The brain was slightly discolored, differing but little from the normal. The brain substance at this point was soft. I explored it some distance with the knife, but no well defined tumor could be found. The tumor, as you see it now, did not show at any time. The process of hardening has brought it out. I took away a small portion of the cortex, in which Dr. Whitney found nothing special at the time. More careful examination of the hardened specimen showed that it was blended with the rest of the brain and that it would have been impossible to distinguish, isolate or remove it. I recall one or two cases of extensive hernia cerebri accompanied by sloughing of a considerable portion of the cortex, and death. Nothing could have prevented it. The operation in this case, I think, was justifiable, though the prognosis was not encouraging on account of the extensive nature and situation of the lesion. If the growth had been a fibroma or any well-encapsulated tumor of a consistence distinctly perceptible, I think I should have attempted to remove it. Giving up the operation at the time I did was conservative, and certainly wise in the light of the subsequent history.

DURING the past season there were twenty-six fatal accidents in foot-ball matches in England.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JULY 27, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

MEDICAL EXHIBITS AT THE WORLD'S FAIR.

AMONG the acres of exhibits at Chicago a casual visitor might easily get the impression that medicine had been neglected. But if everything connected with the profession of medicine were in one place, there would be more than most physicians would care to examine. Most medical men who visit the fair are on a vacation, and do not expect to do more than glance at medical exhibits. The ones which require time to study are often deserted or are being examined by non-medical visitors who are tired of walking through miles of buildings, and who hope to find some exciting pictures or specimens. A physician could well spend several days among the material which is connected with medicine. The collections are scattered, and many of them in out-of-the-way places; but, as a rule, they are carefully arranged, and represent a large amount of work and study.

The Marine-Hospital Service has an exhibit in the Government Building, which is well arranged and contains among other things connected with the service, a bacteriological laboratory in working order. The Medical Department of the United States Army have a small model hospital building between the Government and the Liberal Arts Building. Here there is a drug-room, a hospital bed, a collection from the Army Museum; and on the second floor a clinical laboratory. This building, on account of its position, is generally crowded.

In the gallery of the Liberal Arts Building will be found the exhibits connected with medical education. The most complete of this series is that of the German universities, to which entrance may be obtained by application. The medical departments of Harvard, Michigan, Pennsylvania and Columbia are on the south end of the gallery in the exhibits of the different universities. In the north and long west galleries are many collections of instruments, surgical, optical

and psychological; and many more of these being the exhibits of individual firms, are scattered among the sections or buildings of different countries, and are not well arranged for inspection.

Many exhibits which were originally intended to be in the Liberal Arts Building, and which should have been near the others, are in the Anthropological Building, at the extreme southeast corner of the grounds. This building contains a heterogeneous mass of material, which has not yet been entirely arranged. It is out of the way of most visitors, and consequently does not receive the attention which it deserves. In the southern part of the floor the departments of Sanitation and Hygiene, and of Charities and Corrections are situated. Comparatively few States have contributed anything to these collections; and those which have, have done so in different ways, so that the interest lies in the individual exhibits, and not in comparisons. The State of Massachusetts contributes a large fraction of the whole exhibit. Especially to be noticed is the exhibit of the Massachusetts State Board of Health, a more detailed description of which will be published in an early issue. The number of hospitals represented is very small; the Boston City Hospital and the Johns Hopkins Hospital have carefully-prepared and interesting exhibits. Several insane hospitals, penal and charitable institutions are shown by models or diagrams, and by collections of articles manufactured in them. For a student of public institutions many charts, books and pamphlets are obtainable by application.

A visitor is surprised at the frequency with which the ambulance service of the grounds is used. This service is well organized, and is connected with a system of hospital sub-stations, the headquarters and hospital of which are in the Service Building, just north of the Transportation Building. The thorough equipment of this hospital was shown during the recent fire in the Cold-Storage Building, when a large number of accidents brought in together caused no confusion, and found no lack of medical assistance or nursing.

Exhibitions connected with hospital management and nursing and the preparation of drugs are also found scattered through the State Buildings, the Woman's Building, and in special small buildings. Among these is the Children's Building, in which is a gymnasium and a repository for infants, both in active operation. It is reported that several children, left until called for, have not been claimed, and that the fair has a large stock of these deserted young ones on its hands.

For the student of anatomy, or of art, the fair offers wonderful opportunities for the study of the female form. Statues everywhere and paintings, embroidery and decorative work of all kinds represent the female breast in every variety of size, shape, and material. The male figure is not neglected, and the only object which appears to be prohibited is the classical fig-leaf.

By a wise rule, exhibitions and advertisements of quack medicines have been almost entirely excluded, so that it takes one by surprise to find the advertisement of a sure cure for piles unroll itself on the toilet-paper in the closets. This is one of very few such nuisances; and the dignity of the fair is much increased by the prohibition.

THE THERAPEUTIC VALUE OF ALCOHOL IN PNEUMONIA.

At the Société de Thérapeutique, session of May 24, 1893, the subject of the therapeutic value of alcohol in pneumonia was again discussed. While the necessity of alcohol in the asthenic forms was admitted by all, the general sentiment of the authorities present was in favor of giving alcohol, as such, in its purity, sufficiently diluted. The old notion that old wines, whiskeys, etc., were to be preferred because of the "mellowing" properties conferred by age was condemned as a delusion. Such liquors were declared to be much more irritant to the stomach and less certain in their general supporting effects than pure ethyl alcohol, deprived of aroma.

One eminent speaker commended the alcohol of rice, as being exceptionally free from fusel oil and other impurities.

We are told that the best French cognac is, "with few exceptions," "nothing but the alcohol of beets, of poor molasses, changed and colored by the fabricator by the addition of infusion of tea and various essences which give it bouquet." Such brandies are almost certain to contain methyl alcohol in quantity — certain, when freely administered, to do harm to the patient.

M. Huchard, who is an enthusiastic advocate of the employment of digitalis in the pneumonia of influenza, thinks alcohol the remedy *par excellence* of pneumonia by reason of its "dynamogenous action." There was much speculation as to how alcohol does good. M. Bovet declared somewhat vaguely that "by its dynamogenous action it supports the patient: by its reducing action, it modifies the elements of the blood, which rendered more fluid, undergoes an osmotic acceleration which expresses itself by the progressive decongestion of the pulmonary parenchyma." He also thought that "by its calorigenous reaction, it develops a considerable number of calories which cannot but have an influence on the evolution of the infectious elements, by this fact, impeded in their toxic action, and possibly destroyed, "What tends to prove this," he says, "is that after the absorption of the alcohol, we find in the extractive matters of pneumonia patients an abnormal proportion of waste matters of the creatinic series, which are known to be endowed with a remarkable toxicity."

But apart from such speculations, the best proof of the value of alcohol in pneumonia was affirmed to be clinical experience.

The combination of pure ethyl alcohol with digitalis constitutes, in the estimation of Huchard, the ideal treatment of pneumonia, when any active treatment is needed. He gives the digitalis in the form of its active

principle, the crystallized digitalin, in the daily dose of one millegram by mouth.

It is a little singular that no allusion was made at this meeting to the therapeutic efficacy of strychnia in acute croupous pneumonia, a drug which is coming more and more into favor generally as a cardiac tonic in this disease.

MEDICAL NOTES.

THE PETTENKOFER FESTIVAL. — The fiftieth anniversary of Pettenkofer's doctorate was celebrated in Munich, July 1st. The official festival began at eleven o'clock in the morning in the great hall of the "Rathhaus," which was decorated for the occasion. Pettenkofer was first invested with the insignia of the orders bestowed by the Emperor, the Prince-regent of Bavaria and the King of Servia. A renewed medical diploma was given him by the Munich Medical Faculty, after which a congratulatory address was read from the Imperial Sanitary Commission. The greatest honor now followed in the bestowal by the Burgomasters of the "Gold Bürgers medal." This is the first time that this honor has been given to a person already holding an honorary citizenship, as Pettenkofer does. After this came a long list of addresses from the various schools of Munich, from the universities of Berlin, Erlangen, Freiburg, Göttingen, Halle-Wittenberg, Leipzig, Prague, Vienna and Würzburg; from the medical schools of Amsterdam, Basel, Breslau, Edinburg, Giessen, Graz, Greifswalde, Heidelberg, Kasan, Kiew, Marburg, Rostak, Strassburg, St. Petersburg. Deputations from all the scientific societies were then introduced, who offered congratulatory addresses or honorary membership. At the close of these speeches Pettenkofer's present pupils presented him with a memorial volume or *Fest-band*. In the evening a banquet was served in the hall, which was filled to overflowing; the rejoicing and speaking lasted till midnight.

OFFICIAL DELEGATES TO THE PAN-AMERICAN MEDICAL CONGRESS. — In response to the invitation of the President of the United States, nearly all of the foreign governments have appointed official delegates to the Pan-American Medical Congress. The larger cities of the Latin-American countries have appointed delegates to the sections on Hygiene, Climatology and Demography, and on Marine Hygiene and Quarantine. The United States Government will be represented by six delegates, and the governors of several States have so far named seventy-six delegates.

A BEQUEST TO A PHILADELPHIA HOSPITAL. — The German Hospital of Philadelphia receives a gift of one hundred thousand dollars by the will of the late A. J. Drexel.

AUSTRALIAN HOSPITALS AND THE FINANCIAL CRISIS. — A late and serious effect of the financial distress in Australia is just coming to notice. A correspondent writes to the *British Medical Journal* that the hospitals are in very straitened circumstances since they are largely dependent upon private contributions for their support. The Government grant, which for years has been very inadequate, is in danger of being reduced still more. Some of the hospitals have been obliged to reduce the number of patients admitted, in face of the fact that owing to non-employment more persons than usual are looking to the hospitals for medical care.

DERMOID CYST OF THE LUNG. — A case is reported from Vienna, of a dermoid cyst of the lung. The tumor had its origin in the mediastinum, and after involving the lung ruptured into one of the bronchi, the hairs being coughed up in the expectoration.

NEW YORK.

THE CROTON WATER-SUPPLY. — It seems that the health authorities were rather unfortunate in proclaiming the unusual purity of the Croton Water-Supply. Within the past two weeks the water has become decidedly offensive both in odor and taste, and the latest analyses show an uncomfortably large proportion of albuminoid ammonia, as well as a slight increase in nitrates. In view of the many complaints made, Chief Engineer Birdsall, in compliance with a request from the Commissioner of Public Works, made a report, dated July 12th, in which he says: "During the month of May the long-continued freshets in the Croton water-shed thoroughly impregnated all the water in the streams, reservoirs and distributing mains with suspended matter. The usual remedy of blowing out the water-mains was in course of application, when the dry and warm weather of the latter part of June so increased the temperature in the streets and reservoirs that nature began the usual process of purification by fermentation. This process of natural fermentation usually occupies a period of six weeks, and while it is in progress it gives a muddy appearance and bad taste and odor to the water. Since June 14th it has become necessary to draw 120,000,000 gallons of water *per diem* from the storage reservoir to supply the 163,000,000 gallons daily distributed and used in the city. The stored water always has a musty taste and odor, but its passage through the streams, reservoirs and aqueducts generally purifies and deodorizes the water. At the present time, however, the water running in the streams is undergoing a purifying process, and this, combined with the use of stored water, increases the bad taste and odor. . . . A very heavy and continued rainfall in the Croton basin would remove all of the offensive taste and odor in a week, but as there is no prospect of such rainfall, the improvement in the quality of the water will only be gradual from now on, and the rate of that improvement will also depend upon the conditions of temperature and weather."

NEW YORK BOARD OF HEALTH. — At a meeting of the Board of Health held July 19th, a report was read from Dr. H. H. Doty, Chief Inspector for Contagious Diseases in which he states that he is convinced that a large number of down-town lodging-houses are infected with the germs of typhus fever, and that a

large percentage of the patients who have recently been removed to Riverside Hospital on North Brother Island have contracted the disease in these infected lodging-houses; moreover, that this condition of affairs is the result of an accumulation of the poison, covering a long period of time. The comparatively few cases occurring at present as the result of this infection, he thinks, is due to the increased amount of fresh air which is admitted to the premises during the warm weather and the fact that at this season there are comparatively few lodgers, particularly permanent ones. He therefore recommends, as a means of eliminating this source of contagion that all lodging-houses in the city which appear on the list of typhus lodging-houses on record in the bureau of contagious diseases be properly disinfected by their proprietors, under the supervision of inspectors detailed from the Division of Disinfection and Fumigation. At the conclusion of the reading of the report the Board ordered that the disinfection recommended should be made. At the same meeting President Wilson reported that the results which Health Commissioner Edson had met with in some recent experiments with the Wolf electrical system for the purification of water had been very successful, and that it was probable that the department of public works would have a purifying plant put up, the cost of which would not be more than $5,000.

Immigration Supervision. — In view of the possible advent of cholera the United States Marine-Hospital Service has prepared a system of medical supervision of immigrants until they arrive at their proposed destinations. On each immigrant train that leaves the city there will be a medical representative of the Marine-Hospital Service whose duty it will be to report to Dr. Bellbache, of the Ellis Island immigrant depot, any cases of sickness occurring during the journey. In the event of cholera developing in transit, the patient will be isolated, and the train quarantined.

Pasteur Institute. — Dr. Gibier reports that during the year ending July 1st there have been 104 persons under treatment at the Pasteur Institute, of which he is director, and that among these no death has occurred. Forty of the cases were from New Jersey, a much larger percentage than any other State. The cases are divided into three classes. The first combines those patients who were bitten by animals in which the existence of rabies was proved by means of experiment or by the death of some other person or animal bitten by them. The second is made up of those who had been bitten by animals recognized as rabid by clinical examination, and the third, of those in which the presence of rabies in the animals by which they were bitten could only be suspected, as the animals had disappeared or had been instantly killed, and their bodies thrown away. The first division included forty-seven cases. In commenting on the extraordinarily large number of cases in New Jersey Dr. Gibier states that this is probably due to the fact that there are a great many kennels in that State. He believes, however, that reports of the prevalence of hydrophobia in any particular district are generally more or less exaggerated, and that one reason for this is that it is not an easy matter for the average man to discriminate between rabies and the numerous forms of epilepsy.

Fracture of the Cervical Spine. — There is at present in the Harlem Hospital a young man, twenty-two years of age, who is living with a broken neck and whose prospects for continuing to live are excellent. He was struck by the arm of a windlass, the blow rendering him insensible for a time, and an examination proved that there was a fracture of the fifth cervical vertebræ. Just now the head is supported by a plaster-of-Paris dressing, but before leaving the hospital he will be provided with a permanent apparatus for the purpose.

An Unusual Case of Triplets. — The newspapers report a case of triplets in Nyack on the Hudson which seems to be one of the most remarkable on record. There were two males and one female, and their aggregate weight was fifteen pounds. The two boys were bound together by a band almost precisely like that in the case of the Siamese twins, while the girl was joined to one of the boys by a band passing from the hip of the one to the hip of the other. The children survived for seven hours after birth. When the death of the girl and one boy had occurred an effort was made to save the life of the third child by cutting the ligature binding him to his brother, but it proved ineffectual.

Miscellany.

THE BACTERIOLOGY OF HUMAN MILK.

Since Escherich's report in 1885, it has been believed very generally that the milk of a healthy woman was sterile. His experiments went to prove that only in cases of puerperal fever, did a woman's milk contain bacteria. This view is refuted by Ringel,[1] who has recently concluded a series of experiments which give quite opposite results. He shows that many of Escherich's figures argue against that writer's own theory, as do the later experiments of Cohn and Neumann and Palleske.

Ringel's experiments were carried on in the most guarded manner, and all possible sources of error carefully avoided. The breast and nipple were most thoroughly cleansed with alcohol, 1 to 1000 corrosive solution and ether. Any milk which might have been left in the tubes from a previous milking was drawn off, and the nipple again cleansed. The milk was then drawn into sterile vessels and subjected for twenty minutes to a temperature of 160°.

From 0.25 to 0.5 cubic centimetres of this milk was then spread on nutrient gelatin, and a few drops added to some bouillon and agar.

Milk was taken in this manner from twelve healthy women and from thirteen ill with puerperal fever.

The results were as follows: In three cases the

[1] Münchener Med. Woch., 1893, No. 27.

milk was found sterile; in seventeen there was found the staphylococcus pyogenes albus; in two the staphylococcus pyogenes aureus; once both forms; and in two cases the staphylococcus pyogenes albus and the streptococcus pyogenes. The staphylococci were found, without the streptococci, in eleven healthy and in nine of the febrile cases. The streptococci were found in two cases, one of mild puerperal sepsis and one of phlebitis.

The question of entrance seemed to be answered best by the assumption that the cocci entered from without during pregnancy, and finding a favorable nutrition, developed in excess of the other bacteria which might be supposed to have entered from the air with them.

His conclusions — that "in human milk there are almost always present staphylococci, usually the staphylococcus albus, rarely the aureus; that these have their entrance from without, and produce no particular pathological symptoms in the breast; that besides these forms, streptococci may rarely be found in cases of puerperal fever" — have been to a great extent borne out by Honigmann, in an independent series of experiments.

THE HABITUAL USE OF OPIUM.

IN view of the increasing prevalence of the opium habit in this country, the experience of physicians in India and China is worthy of some attention. The reports recently made to the *Asiatic Quarterly Review* and the *Times of India* are singularly alike in their conclusions.

The smoking of opium is almost universal; and in the observation of over a thousand patients in Johore, Dr. Nightingale found an exceedingly small number who could in any way be considered harmed by the use of the drug. The mild stimulation of smoking was rarely carried to an excess; and when so done, had not the bellicose effects of alcohol. Dr. Lisboa's conclusions were the same: that the habit was much to be preferred to an alcoholic one; that the craving did not grow, nor was the amount used increased as in the case of spirits.

Such, certainly, is not the experience of observers in this country; and it is an interesting question whether the difference is due to the use of the various preparations of the drug in concentrated form, or to a more highly organized nervous system in the Aryan races.

DISLOCATION OF THE SHOULDER.

THOMAS publishes[1] an analysis of thirty cases of dislocated shoulder treated chiefly by means of Kocher's method of manipulation. Twenty-four cases were easily reduced on the first manipulation on the day of the accident. The time occupied varied from fifteen seconds to six minutes; and the reduction was as successful in muscular subjects as in non-muscular patients. Any difficulty in the quick reduction was usually due to a want of steady longitudinal traction or to an irregular tear in the capsule.

The six cases which were unsuccessful at first are especially interesting. No. 1 was of eight weeks' standing; various methods under chloroform narcosis failed, and the patient was discharged with a useful, movable false joint. Nos. 2 and 3 were recent dislocations in spare, non-muscular men; manipulation repeatedly failed, and the heel method was at once successful. In No. 4, manipulation, heel method and circumduction failed; under chloroform narcosis reduction by manipulation was effected in thirty seconds. In No. 5, after the patient was anæsthetized, manipulation again failed, but the heel method was successful. In No. 6, repeated manipulation failed; traction with the patient's arm round the operator's waist was successful.

Several cases were reduced in the first stage, that of outward rotation; the majority, however, yielded in the second movement, of the arm inwards to the chest, while rotation is maintained.

AN OPERATION FOR CLEFT PALATE.

MR. LANE, of Guy's Hospital, has operated upon a case of cleft palate, in which the usual method of closure was impossible, by an ingenious device for obtaining the flaps. The upper lip, the hard and soft palates, were cleft from before backwards. On one side the palate united obliquely with the lower end of the vomer; on the other the alveolus was directly continuous with the inferior nasal meatus.

According to the *Medical Press*, Mr. Lane's procedure was as follows: He removed the mucous membrane from the margin of the hard palate on the one side, and on the other he stripped the mucous membrane from the inferior turbinated bone and from the inferior meatus, and so formed a good-sized flap of mucous tissue and periosteum whose base was continuous with the mucous membrane lining the inner aspect of the alveolus which formed one boundary of the cleft. This flap was then made to cover in the cleft, being connected by a continuous suture with the opposing freshened edge. No attempt was made to close the cleft in the soft palate: it being thought best to wait the development of the hard palate, as the child was only two years old.

INDIGESTION SIMULATING CEREBRAL LESIONS.

CORTIAL reports[1] two cases of acute indigestion which clinically had the appearance of cerebral hæmorrhage.

The first case was that of an ordnance officer, twenty-three years old, of good history and habits. He fell unconscious in the street; and when seen an hour later was insensible, with the eyes rolled up, pupils contracted, a full, regular, fairly rapid pulse and moderate rise of temperature. The extremities were in constant motion, as was the head; but there were no convulsions of an eclamptic nature, nor any discoverable paralysis. The hands were carried to the head as if in pain. Alcoholic intoxication and insolation were excluded by the history; and the diagnosis rested between cerebral hæmorrhage (rare at this age) and indigestion. The stomach was somewhat distended, and pressure over the epigastrium called forth signs of pain from the patient, though still unconscious. On

[1] Archives de Med. Militaires, 1893, No. 7.

this a diagnosis of indigestion was made, and the patient treated accordingly. The bowels were moved, and emesis followed in about two hours, continuing until noon the next day, when the man slowly recovered consciousness, and the case followed the usual course of an acute gastritis.

The second patient, a man twenty-six years old, of good history but for occasional attacks of migraine, was heard to groan in the night, and was found unconscious, with deep stertorous respiration, contracted pupils, and constant movement of the extremities, especially on the left side. As in the previous case, pressure over the stomach caused pain, and greatly increased the movement of the limbs. Similar treatment was instituted; and after copious emesis of undigested food, the patient recovered consciousness, and in a few days was discharged well.

Such attacks, common enough in young children, are not often seen in adults. An important diagnostic point is the tenderness to epigastric pressure. Cortial is in favor of venesection in such cases, having bled both of the patients just reported. That and emptying the stomach is usually sufficient.

THERAPEUTIC NOTES.

PHOSPHORUS IN OSTEOMALACIA.[1] — Sternberg reports four cases of osteomalacia treated with phosphorus; three of which were cured and one greatly relieved. The first was a woman who had been for nearly a year confined to bed owing to pelvic involvement in the disease, was so far cured that during a subsequent pregnancy she was able to go about her work. When confined, there was such firm union of the affected pelvis that a Cæsarean section was necessary, from which she unfortunately died. Two other cases of puerperal osteomalacia made rapid and marked improvement. A case of senile softening in a woman sixty-nine years old, which had gone on to affection of the ribs and kyphosis, made a complete recovery. The phosphorus is given in the following formula:

℞ Phosphori . . . . . 0.05 gm.
Olei morrhuæ . . . . . 50.00 gms. M.
Sig. A teaspoonful daily.

In all his cases Sternberg found that the drug was well borne, and he attributes the negative results of other writers to their having given too small doses.

CREOLIN IN SUMMER DIARRHŒA OF CHILDREN. — In the antiseptic treatment of cholera infantum and summer diarrhœa, Norin reports successful use of rectal injections of warm creolin solutions. He lays the child on its abdomen and flushes the bowel with an alkaline solution, and then injects a solution of creolin of the strength of one-half to one drachm to the pint of boiled water. This is repeated several times in the twenty-four hours, if necessary; but in most cases the vomiting stops, and the diarrhœa is much lessened.[2]

ADMINISTRATION OF CALOMEL. — Chapman[3] urges the administration of calomel in small, frequently-repeated doses (gr. one-tenth to one-sixth every fifteen to thirty minutes) in cases of obstinate vomiting due to gastric irritation. Under this administration two grains have frequently proved enough to allay the vomiting and pain and to do away with the fetor of breath in a very short time. In cases of cardiac dropsy, also, he finds frequent small doses better than single large ones.

SALOL IN TUBERCULOSIS. — Grossi recommends the use of salol in early phthisis in the following manner:

℞ Ol. amygd. dulc. (sterilized) . . . . . 60.0 gm.
Salol . . . . . 10.0 gm. M.

Of this solution five cubic centimetres are given subcutaneously, at first once a day, gradually increased to two or three times each day. He finds that under this treatment the sweating and cough are much diminished, and a gain is made in the general strength of the patient. There is some local induration around the seat of puncture.

FACIAL ERYSIPELAS. — Petrini's treatment of facial erysipelas which, he claims, does away with the need of isolation, consists in painting the affected area with a solution of corrosive sublimate in collodion, one grain to the ounce. After a free purge by calomel and scammony, the patient is given the following:

℞ Quiniæ sulphatis . . . . . ʒ ss.
Iodoform . . . . . gr. vii.
Syr. tolutani } . . . . . q. s.
Ext. gentian }
M. et div. in pil. no. xx.
Sig. Two pills every two hours.

Amesbury	10,920	0	0	—	—	—	—	—

Deaths reported 3,469: under five years of age 1,983; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 1,211, diarrhœal diseases 962, consumption 289, acute lung diseases 193, diphtheria 91, whooping-cough 39, typhoid fever 37, scarlet fever 29, measles 23, cerebro-spinal meningitis 15, malarial fever 11, erysipelas 4.

From typhoid fever Philadelphia 8, Pittsburgh 7, New York and Brooklyn 5 each, Washington 4, Cincinnati 3, Boston 2, Cleveland, New Bedford and Northampton 1 each. From scarlet fever New York and Pittsburgh 7 each, Philadelphia 5, Milwaukee 4, Boston 2, Brooklyn, Cambridge, Springfield and New Bedford 1 each. From measles Pittsburgh 9, New York 6, Philadelphia 2, Brooklyn, Washington, Cleveland, Portland, Worcester and Springfield 1 each. From cerebro-spinal meningitis New York 7, Brooklyn and Washington 2 each, Philadelphia, Worcester, Chelsea and Quincy 1 each. From malarial fever New York 5, Brooklyn 4, Philadelphia and Cleveland 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending July 8th, the death-rate was 23.8. Deaths reported 4,702; acute diseases of the respiratory organs (London) 235, diarrhœa 816, measles 112, whooping-cough 85, diphtheria 76, scarlet fever 54, fever 41, small-pox (London 9, Birmingham 2, West Ham and Bradford 1 each) 13.

The death-rates ranged from 11.8 in Oldham to 42.1 in Preston; Birmingham 26.2, Bradford 24.9, Gateshead 20.1, Hull 20.7, Leeds 21.6, Leicester 32.1, Liverpool 34.9, London 22.4, Manchester 32.2, Newcastle-on-Tyne 25.7, Norwich 13.5, Portsmouth 19.0, Salford 26.1.

METEOROLOGICAL RECORD,

For the week ending July 15, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 15, 1893, TO JULY 21, 1893.

FIRST-LIEUT. JAMES D. GLENNAN, assistant surgeon, ordered to report to the president of the examining board, for examination for promotion.

MAJOR PETER J. A. CLEARY, surgeon, granted leave of absence for four months, on surgeon's certificate of disability.

FIRST-LIEUT. A. E. BRADLEY, assistant surgeon, ordered to report to LIEUT.-COL. DALLAS BACHE, deputy surgeon-general, president of examining board at Omaha, Neb., for examination for promotion to grade of Captain.

FIRST-LIEUT. J. T. CLARKE, assistant surgeon, will, on the abandonment of Camp Poplar River, Montana, proceed to Fort Sully, South Dakota, for temporary duty, and on return FIRST-LIEUT. BRADLEY, proceed to and take station at Fort Omaha, Nebraska.

Leave of absence for one month, to take effect between the 15th and 30th, is granted MAJOR CALVIN DEWITT, surgeon, U. S. A. Par. 2, S. O. 78, Hdqrs. Dept. of Texas, July 11, 1893.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 22, 1893.

T. B. BAILEY, passed assistant surgeon, from Philadelphia Hospital and to the U. S. S. "Machias."

W. M. JONES, medical inspector, from Navy Yard, League Island, and wait orders.

G. H. COOK, medical inspector, to the Navy Yard, League Island.

S. H. DICKSON, surgeon, from Marine Barracks and to the "Dolphin," temporarily.

P. M. RIXEY, surgeon, from the "Dolphin" and granted temporary leave.

J. D. GATEWOOD, passed assistant surgeon, temporary duty at Marine Barracks.

A. R. WENTWORTH, passed assistant surgeon, from the "Atlanta" and granted leave.

W. G. FARWELL, surgeon, to temporary duty on the "Franklin."

C. T. HIBBITT, surgeon, from the "Franklin" and to the "Detroit."

C. W. BROWNELL, assistant surgeon, ordered to Receiving-ship "St. Louis."

APPOINTMENTS.

MALCOM STORER, M.D., has been appointed district physician to the Boston Dispensary.

BENJAMIN TENNEY, M.D., has been appointed district physician to the Boston Dispensary.

PAN-AMERICAN MEDICAL CONGRESS.

SECTION ON MATERIA MEDICA AND PHARMACOLOGY.

A Section on Materia Medica and Pharmacology has been organized under the Executive Presidency of Prof. Joseph P. Remington, of Longport, N. J., with Prof. F. G. Ryan, 3739 Brown Street, Philadelphia, as English-speaking Secretary. Delegates have been invited from all the pharmaceutical societies and colleges in all the Americas. Those contemplating attendance are invited to prepare papers on pharmaceutical topics. Titles should be sent at once to Professor Ryan, Secretary.

CORRECTION.

On page 73 of the JOURNAL of July 20th, the four paragraphs beginning "Mr. Edwin Chadwick" belong under the head of "Vagaries of Sanitary Science," and should be at the bottom of the column.

RECENT DEATHS.

DAVID HARLAN, M.D., died at Churchville, Md., July 12th, aged eighty-four years. He was at one time a member of the Board of Visitors to the Naval Academy at Annapolis, and a Medical Director in the United States Navy.

ANDREW FRANCIS SHEA, M.D., M.M.S.S., died in Lawrence, July 25th, aged thirty-five years.

SPECIAL FRACTURES.

Fractures of the Pelvis. — To go over the anatomy of the pelvis for a moment; the ilium, ischium and pubes, being three separate bones, afterwards consolidate at the acetabulum. The acetabulum is a little Y-shaped piece in the fœtal state, which is an epiphysis. The three bones unite around this little piece. The acetabulum is a weak point in the bone; and up to the period of adult life, if a fracture of the pelvis takes place, it is very apt to run into the acetabulum, in the line of these old junctions. Setting that aside, there are quite a number of epiphyses which are liable to be broken off. The spine, the lip, the crest, the inferior spine, the tuberosity, — those are points likely to give way in the young subject, unless the fracture takes place through the acetabulum itself.

The fractures of the pelvis in the strong person occur usually in consequence of crushing injuries. Something must seize the pelvis and compress it, either laterally or antero-posteriorly, in order to break it, for it is usually quite strong. Persons occasionally get caught between moving cars, or between the wheel and body of a cart; or occasionally when a person is at work trying to bring a vessel into a wharf; or at ferry-landings, where persons jump off in a hurry, and get caught between the boat and the dock. The next most common cause, I think, is the fall of banks of earth. This crushes and compresses the pelvis.

Fracture of the Crest of the Ilium. — The simplest one is the fracture of the crest of the ilium. It gives rise to but few symptoms. The patient feels very sore and lame about the attachments of the muscles of the abdomen, and on examination there is found a displacement inwards of the crest, and mobility. Crepitus can be found. It unites easily. It is apt to unite with displacement inwards. Bandages put on to hold it in place make it worse. The patient should be kept in bed, with sand bags, perhaps, around the pelvis; and be encouraged to lie still without any direct pressure upon the crest of the ilium.

Union takes place in three to four weeks. It always takes place. I think the resulting injury to the patient as regards the use of the part is slight, if anything at all. The danger in all fractures of the pelvis is in injury to the pelvic contents; especially the bladder, and occasionally the rectum. The bladder may be displaced, removed from its delicate cellular attachments, or torn, or ruptured, by a fracture of the pelvis. In the same way the rectum may be wounded; or the delicate spaces around the rectum may be impinged upon by broken bones and effusions of blood, in such a way, as afterwards to lead to a pelvic cellulitis and abscess, if not to absolute peritonitis. The important point, then, about fracture of the pelvis is the condition of the viscera inside; and these are to be investigated carefully both subjectively and objectively.

In investigating fracture of the pelvis we have a much better opportunity to make a complete diagnosis in the female than in the male, because we have by means of a vaginal examination the ability to map out most of the outlines in the adult pelvis, and to seize the parts within, and compress them outside, and see whether crepitus as well as displacement exists. We have this opportunity, in less degree, by a rectal examination, in both sexes. When doubt exists, we should examine by the vagina and rectum in the female, and always by the rectum in the male.

In regard to the condition of the viscera themselves, we can judge about the bladder in two ways: first, by the intensity of the immediate symptoms; and, second, if these do not exist, by the condition of the water that the patient first begins to pass. It is one of those questions we should always ask and have attended to, the first few times the patient passes water after an accident about the pelvis. Where it is absolutely free from blood the first time, there may be blood in the urine the second time. I have seen it occur several times, that the water passed the first time was clear, but the second time it began to be tinged with blood. The patient first passes off the superficial fluid. The leak begins to bleed; then it bleeds enough into the bladder to give blood with the urine on the second passage. So also we await with a good deal of anxiety the first passage from the bowels; whether that will come down free from blood, and demonstrate that the rectum is whole. Of course, in severe cases of crushing of the pelvis, where the parts have been terribly injured, we have immediate symptoms of great collapse. If the bladder is torn, intense and burning pain about the pubes comes on; the patient makes efforts at passing water without success. If the peritoneum has been involved, we have rise of temperature and all the signs of peritonitis.

We have in the vagina and in the rectum invaluable means for diagnosis by making careful explorations.

Fracture of the crest of the ilium requires but little treatment. Other fractures which run through the pelvis require treatment according to location. They all require absolute rest in bed, with the patient on the back, with the knees slightly flexed, in order to relax the mass of long muscles of the leg which take their rise from the pelvis. In addition, it is of extreme importance and comfort that the pelvis should be held together by a firm swathe, which will compress the bones. A swathe is a very awkward affair, and constantly getting out of place; consequently an apparatus made a good deal like bathing-tights is most useful. In order that this may be applied with ease, all the parts must be laced. In that way everything can be drawn firmly together. It never slips out of place. It is constructed with a view of not chafing the patient, or interfering with the action of the bowels. It is made of heavy material, and fitted as one would fit an elastic jersey, or something of that kind, to the limbs. He must lie persistently on the back; and this apparatus must be kept on a long while — two or three months usually, if the fracture runs entirely through the pelvis. If, in addition to this, we are reasonably sure that the fracture has passed through the acetabulum, this treatment alone will not be sufficient; and we must combine with it the ordinary treatment for fracture of the thigh — extension and counter-extension.

The fractures of the pelvis which are the most troublesome are those which pass through the acetabulum

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

— troublesome to diagnosticate and treat — and they give the worst prognosis. The acetabulum being broken through somewhere about its epiphyseal lines, we shall have crepitus and the ordinary signs of fracture about the neck of the femur, but no shortening, and not necessarily any eversion of the foot. Marked eversion, with the femur unbroken, indicates a through and through fracture of the pelvis. Seizing the pelvis with both hands, sometimes, and compressing it, we elicit crepitus. Sometimes we get crepitus on examination by the rectum, or the vagina.

This requires a pelvic band, long rest in bed, and the full treatment for broken thigh, for a considerable length of time.

The result which we get will be union, but probably not smooth and comfortable to the patient. Stiffness of the joint, subsequent arthritis, etc., are common sequences of this fracture. There will be a more or less stiff and uncomfortable hip-joint from the fracture.

Fracture of the Sacrum. — Fracture of the sacrum can be pretty easily detected from the outside, for the sacrum is rather superficial. It can occasionally be detected by examination by the rectum.

It is difficult to restore the position of the sacrum when broken. It may be done possibly by violent pressure from within the rectum. Such cases must be treated by very gentle pressure with a pelvic band, and by keeping the patient in bed. Union is pretty sure to take place. The chance of its breaking through where some of the great nerves emerge is possible, with subsequent sciatica.

Fracture of the Coccyx. — Fracture of the coccyx presents no external signs except that the patient cannot sit down without great distress, and complains of a hard or straining passage from the bowels. Fracture of the coccyx can hardly be overlooked, if we examine properly by the rectum. Passing one finger well up into the rectum and having the thumb outside on the coccyx, you have complete control, and can tell whether there is mobility or crepitus. In addition, we often find that the coccyx is abnormally tipped in; and we can push it back into place. Usually it can be pushed back, temporarily at least, into place. It is important to rectify the position, inasmuch as if left, it interferes with the action of the bowels, causes tenesmus, and is apt to produce neuralgic pains. Coccyodynia is apt to result, and sometimes requires operation to relieve it. I have seen one or two cases of fracture of the coccyx do well under the following treatment: clear out the bowels thoroughly; replace the coccyx into position by the finger in the rectum; keep the patient on the side in bed, and do not let him lie on the back; keep the stools perfectly soft, which is best done by daily small doses of castor-oil.

The slight injuries of the coccyx which happen from persons being thrown from a carriage or sleigh, or falling on some sharp substance, the top of a chair for instance, produce a bending of the coccyx without fracture. They strain the ligaments, bruise the parts, lead to subsequent spasm of the little coccygeal muscles, and to a rheumatic condition, or to some sort of an inflammation of the ligaments of the coccyx itself. This is frequently the seat of long-continued neuralgic pain, and is sometimes relieved by dividing the ligaments; sometimes it has to be treated by excising the coccyx itself, which is not a dangerous operation, if properly conducted, although the hole that is left will surprise you by its depth and size, and take some time to heal up. The average results of any operative interference are not very encouraging.

Fractures of the Neck of the Thigh-Bone.— The neck of the thigh-bone differs very much at different ages. In the young subject it is at a very slight angle from the shaft. In youth it becomes a little more oblique; in adult life it is at a greater angle; in old age it is almost transverse; and in addition to that, it is shortened.

As to the anatomical structure of the neck of the femur, the posterior edge has the thinner wall. It is made up of cancellous tissue partially. The thinner wall being on the posterior part, after moderate injuries it is the back wall which breaks first; and if that gives way, then the femur rotates (just as it would upon a hinge) upon the back wall, and the foot turns out. That is the usual history. In complete fracture across, the foot turns out, from the loss of control of the obturator muscles.

The fact of this different structure of the bone, and its different positions in different ages, apparently explains why it is that fractures of the neck of the thigh-bone, which are complete, are very difficult to make unite again after a certain age. Bony union, it is asserted, almost never takes place beyond the age of sixty. I have seen what I supposed to be bony union at the age of fifty-four, or fifty-five. Even when a person has passed fifty, judging by the constitution and the relative age, we may infer whether they will have sufficient vigor to unite the fracture of the neck of the thigh-bone by bone.

Various reasons exist why this should be difficult to do. In the first place, the upper fragment, as you see, is like one-half or two-thirds of a billiard ball, lying in the socket, bathed in the synovial fluid, having no nutrition except that coming from the ligamentum teres. When there is a complete fracture, the neck rides out of the socket; the femur is gradually drawn up out of the socket; the limb is very much shortened; the parts do not come in apposition; and it is difficult to keep them in apposition, indeed, by treatment. Not only does shortening take place, but, in addition to that, the femur drops back by gravitation as the patient lies in bed.

Want of apposition, want of perfect nutrition, and the general feebleness of the parts, are the causes of failure of good bony union in this fracture.

On the other hand, there is another species of fracture of the neck where separation of the fragments does not take place. This is called impacted fracture of the neck of the thigh-bone: and it occurs from the strong bony tissue of the shaft being driven into the neck and head; the posterior wall of the neck, which is the thinner, giving way; and more or less impaction taking place at a greater, or less angle. By that I mean that this may possibly take place, with the foot directly forward, or in the position of moderate or extreme eversion, according as the bone is driven in posteriorly, as you must see.

Impacted fracture of the neck of the thigh-bone takes place at the same age as the complete fracture; and it is much more likely to occur in the middle-aged and old than in the young; just as in the fracture of the anatomical neck of the humerus, it is especially in middle life and advanced age that that occurs. In extreme youth the epiphyses separate; in adult age the bone breaks at the surgical neck.

The force required to make the neck of the thigh-bone crumble or yield, either to impaction or fracture,

is sometimes so slight, in advanced age, that the theory has been advanced, when a person falls and a break is found, that the fall is subsequent to the fracture. Sometimes, probably, this is true; for the violence of the fall is occasionally so slight that you can hardly consider it enough to produce fracture. Old women will sink down on the floor of a softly-carpeted room, perhaps a distance of two or three feet, and be found to have either impacted, or complete fracture of the neck of the thigh-bone. The slightest possible accidents seem to be coincident with this fracture. Whether they are always the cause of them we have no means of knowing; or whether, possibly, the bone may give way first.

Moreover, there is another very deceptive point. It is this: that in these fractures when the patient merely slips down on the ground, as happens sometimes, the patient is not at first rendered so helpless but that he or she can stand, or walk a few steps, after an impacted fracture; but not after complete fracture of the neck of the thigh bone. Instances are known in which patients have ascended two or three steps of a flight of stairs, before giving out.

A great deal of importance has been laid, as to the chances of bony union and good repair, on the fact whether the line of fracture, in a complete fracture of the neck of the thigh-bone, was entirely inside the capsule, outside the capsule or partially inside and partially outside. A fracture outside the capsule of the neck, outside the socket-joint, is as likely to unite by bone as a fracture of the shaft, or of the trochanters themselves. In proportion as we approach a complete intracapsular fracture, we approach a point where non-union is liable to occur; but to diagnosticate the exact running of a fracture partially inside and partially outside the capsule is probably beyond our knowledge. Some authorities pretend to do it. There is an anatomical peculiarity which is well recognized and has been written upon, which rather gives discredit to this assertion. It would be, in the first place, down through the deep tissues of the buttock, extremely difficult to tell exactly where a fracture had gone with reference to the capsule, even if we knew the exact position where the capsule is. We know where it ought to be. It varies. In some joints it is higher; in some it is inserted lower upon the neck; and if you take this doubtful anatomical position of the capsule itself, and the difficulty of detecting a fracture which may run one-fourth of an inch one way or the other, above or below the neck, you must see the difficulty of the diagnosis of partial intracapsular fracture from entire intracapsular fracture. It is quite clear when we get a fracture outside; we can recognize crepitation directly under the trochanter, and other signs; but when it gets in the vicinity of the capsule, to tell whether wholly inside or out, I am inclined to think is beyond the ordinary run of wisdom, or of guessing.

Symptoms of these two classes of injuries. They are sometimes so slight that they are unfortunately overlooked. The patient has a fall the like of which he has had many times before without sustaining the least injury. He becomes incapacitated; sees he or she cannot walk; and the friends, and often the physician, are ready to ascribe it to a contusion, or bruising, or neuralgia of the part, rather than to a fracture. The subsequent symptoms at first are so slight, that this sort of fracture is very liable to be overlooked.

The impacted fracture. The patient has a very slight slip or fall. He gets up and steps a step or two, and he says he cannot go any further. On being examined it is rare that any bruise of the external parts is found. Such patients usually fall with a good deal of clothing on; and on some place perhaps where it is soft, and a bruise is not common as it is in other fractures. Subsequent swelling comes on; but that is after a day or two. There is not much to guide to the seat of the injury except the nature of the fall and the nature of the pain, which is marked and localized. On having such a patient put to bed and the two legs carefully compared, it will be found that there is a slight shortening and considerable eversion. Great eversion is not always the fact; and occasionally the foot may even be inverted, in some forms of impacted fracture. We should readily distinguish the inversion of this fracture from the inversion of a dislocation on the dorsum, from the fact that in dislocation on the dorsum we must have a shortening of one and a half to two inches, and in this fracture we should have a scarcely appreciable shortening, one difficult to measure; one-eighth to one-fourth of an inch, perhaps, marks the outside limit in the simple impacted fracture of the femur. One-fourth of an inch is the common thing, and with moderate eversion, inability to rotate the foot in. They can move the toes in if they make great effort. In addition to this we should not gain much by rotation of the trochanters, because although the arc of the circle through which it sweeps may have been shortened, it is not like the spindle-shaped motion when the shaft is broken completely off. In impacted fracture, then, with slight shortening and eversion, if we examine here and rotate, we shall not appreciate much difference in the arc of rotation from the normal state. These are about the only signs; and they are very slight. If such a case is overlooked, the patient will struggle to sit up, and will be taken out of bed into an easy-chair and begin to try to move about; and, either after a long time the part will slowly recover at the expense of a great deal of pain, or what is more common, the first violent motion of any kind will produce a complete fracture. Total disability will follow, and complete eversion, and a powerless and shortened limb. This, then, would emphasize very much the importance of not churning about such a suspected fracture too much to get crepitus; for if we have converted the impacted into the complete fracture, we have added very possibly a ligamentous union.

A slight injury, very slight, no bruises; the patient is not able to believe at first that anything could be broken; tries to stand, has to give it up; has great pain (being already fifty-five to sixty years of age); he is found to have slight eversion, slight shortening, inability to rotate the foot in, pain localized perfectly about the neck of the femur; and that is all. Those are the symptoms of moderate impaction.

On the other hand, in the complete fracture of the neck of the thigh-bone, as a rule, the patient has a similar fall, not necessarily a more violent one. It depends upon the age of the patient, condition of the bone, and the reception point of force, whether or not he will get a complete or impacted fracture.

The signs differ a good deal from those of impacted fracture, and the signs are very important to distinguish between these two.

Complete fracture usually gives a shortening of one

to one and a half inches. At first this shortening does not take place. It comes on gradually. At first we have slight shortening with eversion and helplessness. The next day shortening will take place, unless some treatment has been applied to draw the limb down. In addition to this the foot is laid off in an everted position. It is completely helpless. The patient can hardly lift the outer side of the foot from the edge of the bed, and cannot invert it to anywhere near the extent he can in an impacted fracture. Pain is great on manipulating the limb. If ether is given, in the early stages, by drawing down gently, and bringing the shaft opposite the neck, we shall generally get crepitus; but we shall get at any rate one other sign, and that is, examining the trochanter, we shall find instead of sweeping through its normal arc, it merely rotates feebly. We can get it more particularly if we seize it; and with the patient etherized, and a person taking the knee, we can see whether this bone rotates through the arc of a circle which comprises several inches, or merely turns on itself. If the latter, you may be quite sure that the neck of the femur is broken off. In addition to this, if the case is untreated for ten or twelve hours, you will have increasing shortening, until it amounts to one, or one and a half inches, in very many cases. We all know how difficult it is to make an accurate measurement as to shortening; and a number of observations must be made and the mean taken. Great care must be taken to place the patient exactly straight on the bed, to have the limbs alike, to have the everted foot held up so as to correspond to the other, that the knees shall be down flat, that the patient shall have no pillow. The surgeon should look at the patient from the foot of the bed, and see if he can draw a line directly through the body to the axis of the head, and then proceed to measure from the anterior superior spine to the inner condyle, and from the umbilicus to the inner condyle; and usually he will detect shortening by both of these measurements, sometimes not exactly corresponding. If one gives one-half inch, and the other three-fourths, he must compromise, and conclude that the true shortening lies between these. This is of no matter one way or the other, except for purposes of diagnosis; and in that way it is of considerable importance. We know when the femur is drawn out of the socket on the dorsum, that it is pulled up and shortened a couple of inches. When we get a fracture of the shaft of the femur, we get deformity in the contour of the limb and great shortening at once. On the other hand, when we get a fracture, impacted, of the neck of the thigh-bone, we get very slight shortening, with eversion; and with complete fracture, considerable shortening after a time, but not at the first moment when the accident occurs. Do not be deceived into the idea when you are first called to a suspected fracture of the neck of the thigh bone, that it cannot be wholly broken off because at first considerable shortening does not exist. You must take all the signs together; examine carefully again during the next twelve hours, and you will probably arrive at an accurate conclusion.

In addition to the chances of getting no union, the patient, if advanced in life and at all of the rheumatic diathesis, is liable also to have a great effort of nature to throw out bone in the wrong place. She will not join the broken part; but throws out bony growths about the socket, and perhaps about the trochanters; the result of which is indurations, bony osteophytes occurring at various points, pain, and more incapacity of the limb than if the patient had not undergone this rheumatic change. We have got to take that into account in making a careful and guarded prognosis with regard to the future utility of a hip-joint injury in an old person. This change may come on after impacted fractures; and it is not safe to say to the patient, "Your bone is cracked, not broken off, and in a few weeks it will join and be as useful as ever," for that is not always the case. In addition to this, a great many of these patients suffer from sciatica, which is annoying, exhausting to the patient, leads of course to wasting and non-use of the muscles about the hip, and subsequent more feeble use of the limb for a long while. This also has to be taken into account.

Now, as to the treatment of these two classes of injuries. It is evident that every effort should be directed to prevent an impacted fracture from being separated from the place where it has been forced in. We are willing to have a little shortening, to have eversion, provided the impaction can stay; because that assures us of a firm bony union. To extend the limb by weights is to risk breaking it off. No extension should be used after an impacted fracture, except with the idea of steadying the limb. It is important that the parts should be held still; and it is best accomplished by the pelvic belt. Put a pad up behind the trochanter, which they cannot shift about and lie on — a pad of hair or cotton, or a little sand bag, which will hold the weight of the trochanter up; the pelvic belt; and additional sand bags to lie about the limb to correct the eversion as far as possible, and to keep the patient as still as possible. In this impacted form, this mode of treatment seems to give very fair results. If we can get along in the old person without long internal or external splints or extension, we by so much diminish their suffering, and the chance of bed-sores, and they generally do better and get about sooner. In the impacted fracture, when we are quite clear about it, we should not manipulate it too much; should support the back of the trochanter; support with a pelvic belt, use sand bags and rest. Six weeks usually will suffice to get it into the condition where the patient can sit up in a chair. After a while the neck will get quite strong; and with the exception of slight shortening and slight eversion, the patient frequently does very well.

On the other hand, in the complete fracture of the neck of the thigh-bone, we cannot be quite sure whether we are to have bony union or not; and we know that if we let the part alone, the muscles within the next twelve to thirty-six hours will pull the lower fragment far up beyond the upper one and produce shortening, and that no union can take place because the parts are not in apposition. Moreover, in addition, this muscular contractility keeps the patient in constant pain; and therefore in this particular injury, at any age, I am inclined to think a moderate extension by weight and pulley, for a while, at least, is a useful mode of treatment. It overcomes muscular spasm; overcomes the pain; draws the parts down into contact; keeps them at rest; puts them in a position where they can unite, if there is any union to take place. The objection against using extension and apparatus on these old people is that occasionally the shock and confinement kill them; and where they show any signs of flagging we should accept the fact that the chance of

life is better than any disability about the hip. We should take off the apparatus, and put them on the double-inclined plane chair, perhaps. In that way we may save life; prevent disasters by sores; retain for them, perhaps, control over the bladder, which is frequently lost; and they may live a number of years. If they are strong enough in the arms and shoulders they get along; for they will be able to use crutches and go about. Many of them live for years, and go about on crutches, with a ligamentous union and a dangling and everted foot. That is the reason why it is sometimes dangerous to use extension; but if the patient can tolerate extension, I am inclined to think a moderate degree of it is indispensable in the early treatment — not applied with the same rigidity or hope of union as we should in fracture of the shaft of the femur, but as a conservative measure to relieve the spasm and pain, and to put the fragments in proper position, and, in addition to that, to keep the parts quiet until nature makes the next change, which she makes if union is going to fail. This change consists in rounding off and smoothing the fragments and leading to a sort of fibrous union; and after that change has taken place, the parts are no longer painful; do not rub together; slide smoothly on each other; and are protected by a species of false membrane. Extension can then as well be taken off as not, for no further relief is to be expected from it.

In old times the whole treatment of fractures of the lower extremity was so much more rigid than now, that the patients, even in vigorous life, frequently got bed-sores, frequently got bad ulcerations of the perineum from the straps that were applied for counter-extension, not infrequently sloughing of the heel from the foot being held in a firm box so long. No wonder that the older surgeons, seeing these disasters in strong subjects, should find that they were pernicious and fatal to an old person.

Now, on the other hand, we have fortunately altered that, and the treatment of fractures of the lower extremity is not so severe. Bed-sore is rare. Sloughing of the heel is practically unknown. I have not seen one for many years, in treating fractures. The perineal strap has been wholly abandoned. The modern treatment of fracture of the thigh is extension by weight and pulley; raising the foot of the bed; preventing rotation outwards of the limb by a long splint or sand bags; and this can be much more safely applied to an old person than the former harsh treatment could be.

These are the arguments, pro and con, in treating complete fracture of the neck of the thigh-bone. Moderate extension, carefully applied, is useful, for it may lead to union. If union has failed to take place after six or eight weeks, there is not the slightest hope of its taking place. Then extension should be abandoned, and the patient got up on crutches; and massage should be used to strengthen the muscles about the joint.

In a certain proportion of cases we shall be annoyed by the persistence of roughness and grating in and about the joint, which is not due to the fracture, which has been rounded and softened in a false membrane, but to the occurrence of chronic rheumatic arthritis. That is the bane of this class of injuries; and it is difficult to do much for the comfort of the patients, unless they can wear some sort of leather splint or support, which will prevent much motion of the joint; or are sufficiently strong to wear a Sayre's apparatus, which extends the leg a little, and allows the patient to walk without much motion or friction in the joint itself.

TUBERCULOUS PLEURISY.[1]

The Shattuck Lecture for 1893.

BY WILLIAM OSLER, M.D.,
Professor of Medicine in Johns Hopkins Hospital, Baltimore.

(Continued from No. 4, p. 85.)

Case IX. Cough and hæmoptysis a year before; gradual onset of the effusion; repeated aspirations; tubercle bacilli found in the exudate; subsequent development of pulmonary tuberculosis.

Christian T., aged thirty-nine, German, admitted September 25, 1889. Patient is a large, well built, muscular man, very well nourished, with thick panniculus adiposis. With the exception of measles as a child, chills and fever in Germany, and a chancre with mild secondaries in 1884, he has enjoyed excellent health. No history of pulmonary trouble in his family. His wife died of consumption four years ago. He was very well and strong until about a year ago, when he had cough with much expectoration, and on one occasion he spat up a mouthful of blood. In January, 1889, he lost in weight, and for the first time began to be short of breath. He had no pain, and was able to be at work, but on any exertion he became breathless, and he states that this has been his chief symptom, and for it he now seeks relief. He does not think that he has had any fever; temperature on admission was 98°. The patient looks in excellent health; weight about 160 pounds; pulse is 72; tongue is clean. The chest is large, well formed. On quiet breathing there is no special difference noticed, but the right side looks fuller than the left. When he draws a deep breath the right expands very slightly. The apex beat of the heart is visible in the fifth interspace, but an inch and a half outside the nipple line. The intercostal spaces are not marked on either side. From behind, the right side of the chest looks fuller than the left. On palpation there is absence of fremitus on the right side, except just below the clavicle, and there is absolute dulness from the clavicle down, and anteriorly it extends to the left border of the sternum. Breath sounds are feeble and distant on the right side, except in the lower interscapular space, where they are tubular and distant. On the left side the breathing is breezy and loud. On the 28th, 30 ounces of clear fluid were removed. On the first of October the dulness was practically the same, and 30 ounces were again withdrawn. This time it was more turbid. On the 6th he was aspirated again; 25 ounces. Cover slips and cultures were negative. His general condition all this time was excellent. He was up and about the ward, and the temperature was normal. On the 11th he was again tapped, and 32 ounces of fluid withdrawn. He had a very slight cough with much muco-purulent expectoration, which was examined daily for seventeen successive days without discovering bacilli. Although the history of an attack a year ago, with cough and hæmoptysis, raised a suspicion that the process might be tuberculous, there was nothing whatever to guide us to that conclusion; and it was not until he had been

[1] Delivered before the Massachusetts Medical Society, June 13, 1893.

under observation for nearly three weeks, and his convalescence was practically established, that tubercle bacilli were found.

On the 18th he was aspirated and 32 ounces were withdrawn, and the note became clear as low as the nipple. On the 27th 19 ounces were removed. On November 7th the note reads: "The right lung is fairly resonant to the fourth rib, and in axilla to eighth, posteriorly to middle of scapula." The fluid again accumulated, and on the 16th 28 fluid ounces of a greenish-yellow, slightly turbid fluid were removed, in which tubercle bacilli were found by two separate observers on the 16th and 17th. The measurements on the right side, 19 inches, on the left 18½ inches. On the 14th he was aspirated for the eighth time, and 32 ounces of fluid removed, of the same clear character. The note was resonant to the fifth rib and behind to the middle of the scapula. In these regions the breath sounds were loud and free from râles. Cultures from this fluid remained negative, and no bacilli were found. Patient gained in weight, lost the cough entirely, and was only short of breath when walking fast. Appetite good; sleeps well. He decided to go out, and was discharged December 19th. At the time of his discharge resonance was clear and a little high-pitched on the right side to the third rib in front; below this there was absolute flatness. Behind it is high-pitched to spine of scapula, and below the note is flat; left lung clear. Breath sounds are normal. This patient was under my observation on and off in the dispensary for many months, and at first seemed to do well. Subsequently he was lost sight of, but I heard that he had developed extensive tuberculous disease of the lungs.

CASE X. Cough for several years, but good health; gradually shortness of breath; right-sided pleural effusion; repeated aspiration; great improvement; discharge: subsequent detection of bacilli in sputum; development of pulmonary tuberculosis.

Henry H., stevedore, aged thirty-six, admitted June 13, 1889, complaining of severe cough. A sister and one brother died of consumption; father of asthma. The patient has been an extremely healthy man, and looks vigorous and well nourished. He states, however, that he has had a cough for many years, certainly for as long as three years. He has been getting short of breath lately. Patient is not at all anæmic; chest is well formed; the right side looks full, and is almost motionless on deep inspiration; the apex beat is in the fifth interspace, two inches outside the nipple line. The left side measures 19 inches, the right 20 inches; expansion on the right side is scarcely a quarter of an inch; on the left over an inch. Percussion gives on the right side a dull note to the clavicle in front, behind to the top of the lung, and to the left a little beyond the mid-sternal line. The left side is resonant. Tactile fremitus is very much lessened, but on saying 99 it is not entirely absent on the right side. Breath sounds are distant, feeble, scarcely audible. Whispered voice over the dull region behind is not heard. Exploratory puncture shows a thin, greenish-yellow, sero-purulent fluid. The following day he was aspirated and 2½ litres of fluid withdrawn; the accumulation was rapid, and on the 17th the condition was very much as before. He was aspirated again, and 32 ounces of fluid removed. This fluid was greenish yellow, with many fat molecules. The fluid re-accumulated rapidly, and he was aspirated again on the 19th with a withdrawal of 32 ounces, and on the 22d with a withdrawal of 29 ounces, and on the 26th with a withdrawal of 27 ounces. On the 29th it was noted that in front percussion is now clear to the level of the nipple; dulness from this point down. Posteriorly it is clear to the middle of the scapula. There are fine crackling râles in the axilla, distant breath sounds over the dull area. By the 8th of July he had improved so much that he was discharged. The heart impulse was in the fifth interspace, just below the nipple, and there were marked friction sounds in the left mammary region and in the scapular region behind. The cover slips and cultures made by Dr. Abbott from the fluid were negative. When he entered the hospital the sputum was abundant, sero-purulent, and was examined repeatedly with negative results. Subsequently his cough lessened and expectoration was more scanty, thicker, and grayish yellow in color. At no time did the temperature rise above 100°, and it was usually between 98° and 99°.

He left the hospital with a diagnosis of pleurisy with effusion, and though there was a suspicion, based chiefly upon the fact that he had had a cough for so long, the diagnosis of tuberculosis could not be positively made, and he looked such a vigorous, healthy man that it did not seem likely. He attended in the dispensary, where I saw him repeatedly. On the 20th of July it was noted that though the apex beat was just below the nipple in normal position, there was everywhere defective resonance over the right side, not absolute flatness, and everywhere from the second rib down there could be heard a loud, leathery, creaking friction. He remained in very good condition, though the cough still persisted. He had no fever. On September 10th tubercle bacilli were found in his expectoration. The leathery, creaking friction persisted, and the defective resonance on the left side. He had lost somewhat in weight, and the cough had become aggravated. On September 4, 1890, I made the following note: There is marked depression of the right shoulder; shrinkage of the right chest. Heart is a little drawn over; impulse in left parasternal line. The resonance is defective above, and shades to dulness below the level of the fourth rib. The tactile fremitus is felt to the base. At the right apex the breath sounds are somewhat feeble; there are numerous râles on coughing, and on drawing a deep breath the sounds are amphoric. Marked cavernous breathing at the apex behind. The breath sounds are feeble over the whole of the right base. Patient was under observation throughout 1891. He constantly had cough, and lost a good deal in weight. On the 22d of June the note was: He still looks well; the feet swell at intervals; temperature normal; the right chest more contracted and the spine is curved. Even on deep inspiration there is very little mobility. Marked cavernous signs at the right apex. There is no note of the patient after this date.

CASE XI. Pleurisy five months before; acute onset of second attack; effusion on left side; gradual recovery; detection of tubercle bacilli in sputum, three and a half years after signs of disease at both apices.

The following case illustrates the importance in diagnosis of a systematic examination of the sputum:

Jos. A., aged twenty-nine, German, admitted July 1, 1889, complaining of pain in the chest, cough and shortness of breath. A brother died of consumption in 1885. Parents dead, but not of tuberculosis. The patient was well as a boy and enjoyed excellent health.

Five months ago he had an attack similar to the present one; was ill in bed for two weeks. He got quite well, but it left him with a little cough. Present illness began six days ago, June 24th, with fever, chilly feelings, and slight cough. He worked until the 29th, and only went to bed yesterday; temperature on admission 102°; respiration 40; pulse 96. Well-built, healthy looking man. Chest well formed, movements equal in upper zone, less on the left side below; most evident on deep inspiration, when the difference in expansion is also very noticeable. Tactile fremitus is much lessened at the left base. There is a hyperresonant note at the left apex, extending into mammary region and axilla, which shades into dulness below the seventh rib, a dulness which is extremely movable and ascends when he sits up. Behind, it reaches to the middle of the scapula. Distant, tubular breathing over the dull region. No friction. Sounds on the right side clear.

Apex beat of the heart not palpable; sounds clear. Dulness in the sitting posture at the level of the fourth rib; movable dulness very marked. The temperature 101°; the cough is better; sputum is muco-purulent, and does not contain bacilli. On the 8th the temperature had fallen to 98°. The effusion had not increased, and the movable dulness is now more difficult to obtain. Though there were a few râles in the left infra-clavicular space, there did not appear to be signs of any cavity. The pleural effusion gradually diminished, and we were inclined to regard the case as one of simple pleurisy. He still had cough, with streaked mucoid and yellowish expectoration, and in it, on the 18th, well-characterized tubercle bacilli were found. He improved very much, and on the 22d decided to go out. On the left side the resonance was clear to the sixth rib. There were sub-crepitant râles over the third rib, and in the lower axilla slight friction sounds. There was dulness in the infra-scapular region, diminished tactile fremitus, and feeble breath sounds.

This man was lost sight of until February, 1893, of the present year, when he applied at the dispensary, complaining of cough and pains in the chest, and diarrhœa. He has kept pretty well since his attack in 1889, and has been at work. He is now fairly well nourished. He has very slight expectoration, and none could be obtained for examination. There is rather a high-pitched note over both apices and there are moist râles, greatly increased by coughing.

The effusion in these cases is sero-fibrinous, often has a greenish tint, is sometimes a little turbid. The fluid is not hæmorrhagic so frequently as in the more acute cases. Bacteriologically it is commonly sterile, though in the case of Christian T. tubercle bacilli were found in the exudate itself.

Sero-fibrinous pleurisy, occurring in the course of pulmonary tuberculosis, does not interest us very much. The cases are by no means uncommon, and the diagnosis is readily made. It may be a very early complication and overshadow in great part the lung disease. The insidious onset and the absence of pain in the side not infrequently lead to errors in diagnosis, and the increasing shortness of breath may be attributed to advance in the original disease, or even to a general tuberculosis. It has seemed to me that the early implication of the pleura, even with recurring exudation, gives a stamp of chronicity to the case. Sometimes it is difficult, even post-mortem, to determine which has been the primary disorder, as in the following case; though, from the great thickening, it is probable that the affection of the pleura preceded the disease at the apices.

CASE XII. Extensive pulmonary tuberculosis; chronic tuberculosis of right pleura.

Alice S., aged twenty, colored, admitted October 12th, complaining of cough, shortness of breath, and weakness. She knows nothing of her family history, further than that her mother died of asthma.

Patient was healthy as a young girl. About four months ago she had a child; was in bed for eighteen days. Her present illness began, she thinks, about a month ago. She has had a cough, but has been able to work until three weeks ago. Says she has only been spitting "thick stuff" for about two weeks, and during this time she had had a great deal of shortness of breath.

Present condition. She is emaciated; much more so than is consistent with a history of an illness of such short duration. The thorax is long and narrow. The clavicular depressions are marked. The expansion is more marked on the left than on the right side. Briefly, the physical examination gave — at the left apex, signs of an extensive cavity, with cracked pot sounds, and amphoric breathing; at the right apex there were indications of a smaller cavity. Behind, there was marked dulness in the supra-spinous fossæ, and impaired resonance over the whole of the right side below the spine of the scapula, with feeble breathing, and râles only on full inspiration. The abdomen was swollen and tympanitic; no signs of effusion.

The patient had an irregular, hectic fever; her pulse was very rapid; she failed progressively, and died on the 18th.

Post-mortem (by Dr. Flexner, abstract). The pericardium is adherent to the right pleura, but is itself smooth on both of its layers. The right lung is universally adherent; the left is adherent at apex and in places behind. The left lung presented a large, irregular cavity at the apex, numerous groups of miliary tubercles and caseous masses, with small cavities in the middle and lower lobes. Where adherent, the pleura is not specially thickened.

On the right side, the pleura is everywhere adherent; the entire lung is much reduced in volume, and measures only 12.5 cm. in length. The top of the upper lobe is occupied by an irregular cavity lined with slate-colored granulation tissue. The pleura of this lung is enormously thickened, more particularly the costal layer, which measures 9 mm. on the side, and about 11 mm. on the diaphragm; and in other places it is at least 2.5 cm. The thickened membrane is uniformly yellowish in color, and shows cheesy masses. Where the visceral and costal layers are not adherent there is fibrinous exudate on both surfaces, which, when scraped off, shows tubercles on the membranes.

The bronchial glands are coal black in color, and caseous. There is marked intestinal tuberculosis, and the retro-peritoneal glands are enlarged and caseous.

(b) With Purulent Exudate.

I have already spoken of the acute purulent form of tuberculous pleurisy. Such cases, however, are rare. The purulent tuberculous pleurisies are much more commonly subacute in onset, chronic and latent in their course. The effusion is usually sero-purulent,

thin, and contains a large amount of fatty matter. It is somewhat interesting to note that among the 32 cases in which tuberculous pleurisy of one form or another was present in the cases examined post-mortem from my wards, there was not an instance of purulent effusion, except in pyopneumothorax secondary to tuberculosis of the lung. In the non-tuberculous cases there were but two with purulent exudate, one consecutive to an acute croupous pneumonia, in a case, oddly enough, of tuberculous peritonitis; the other, in an old man with arterio-sclerosis, who had a purulent effusion on the left side and a sero-fibrinous pleurisy on the right. In both instances pneumococci were found in the exudate.

Our clinical reports embrace ten cases of pyopneumothorax, of which eight were tuberculous, and which, of course, do not interest us specially in this connection. Of the 16 cases of empyema, nearly all of which were transferred as soon as possible from the medical to the surgical side, there was a history of tuberculosis in the father or mother in five cases; in one case two sisters died of tuberculosis; and in one an aunt. One case followed cancer of the pancreas, and one was in an old man with arterio-sclerosis; four cases followed pneumonia. Of the 14 cases which were operated upon, 12 left the hospital either perfectly well or very much improved. The only death was in the instance of empyema secondary to cancer of the pancreas. Unfortunately I have not full particulars of the bacteriological examinations made in all of the cases. The details of the early ones, taken by my late assistant, Dr. Meredith Reese, have been mislaid since his untimely death; so that, from our personal experience here, we can draw no conclusions as to the number of these cases in which the lesion really depended upon the presence of tubercle bacilli. I would again refer to the somewhat interesting circumstance that, with the exception of the pyopneumothorax cases, not a single instance of tuberculous purulent pleurisy was met with in the 101 autopsies in which pleurisy of one form or another was present.

(c) *Chronic Adhesive Tuberculous Pleurisy.*

The special feature of chronic tuberculous pleurisy is the enormous thickening of the serous layers. In all the cases of chronic sero-fibrinous exudate the visceral and parietal layers were greatly thickened. Post-mortem, we see three varieties of this form.

(1) Primary proliferative tuberculous pleurisy. Any one of the three great serous membranes may be primarily affected in tuberculosis, though probably in the majority of all these instances the affection of the lymph sacs is secondary to that of the glands in connection with them, or the organs which they ensheathe. In this form the tubercles developing in the pleural and pericardial membranes cause early union of the surfaces, and there is never at any time a free exudate. With the progressive growth of the tubercles the layers become greatly thickened, and united may measure from one to two or more centimetres in diameter. On section the thickened membranes seem to be made up of diffuse tuberculous tissue, sometimes caseous layers and much fibroid tissue. In the early stages of the process, gray and grayish-yellow tubercle nodules are seen. With the exception of involvement of the bronchial glands, this may be the only tuberculous process in the body. It may be unilateral or bilateral. I have seen but two instances in which it was strictly confined to the pleura, without any sero-fibrinous exudate. One was a young, vigorous Irish girl, who had recently come to the country and was admitted to my wards at the University Hospital, Philadelphia, and died on the third day of an attack of malignant scarlet fever. The pleural layers on one side were enormously thickened and in the condition just described. The other instance was a case of typhoid fever, which died under the care of my colleague, the late Dr. Ross, where the young man had bilateral chronic adhesive tuberculous pleurisy without any effusion. It is not infrequent to see this condition in part of the pleura, with pockets of a sero-fibrinous or curdy exudate at the sides or back, or on the diaphragmatic surface. Dr. Flexner showed at the Johns Hopkins Hospital Medical Society, a remarkable case, to which I shall refer again in a few moments, in which both layers of the pleura, but particularly the costal, were enormously thickened, and miliary tubercles and larger cheesy masses were present. On the diaphragmatic surface alone there was an encapsulated sero-fibrinous exudate.

(2) Much more commonly, with very great thickening, and in the upper zone, perhaps, union of the pleural membranes, there is separation of the layers below and on the diaphragmatic surface, by an exudate usually sero-fibrinous, but sometimes containing curdy or even cheesy material. Thus of the 32 cases presenting post-mortem tuberculous pleurisy, there were 12 with very greatly thickened pleural membranes and sero-fibrinous exudate. Of these six were in connection with old pulmonary tuberculosis. As in Case I, referred to under the acute form, the onset may be abrupt as in acute pleurisy. The membranes gradually become greatly thickened. In that case there was an encapsulated serous effusion over the postero-lateral part of the left pleura, and in the rest of its extent the two layers had united and ranged in thickness from one and a half to two centimetres. In connection with this variety there are two points of very great interest. In the first place it may be extremely difficult to recognize at sight that the process is tuberculous. In this very case of John A., who had been under our care and tapped repeatedly two and a half months prior to his entrance to the hospital with an acute pneumonia, it was only the closest examination of the dense, thickened pleural membranes which revealed old fibroid tubercles. A superficial, macroscopical examination might have entirely overlooked the tuberculous character of the process, as the lung on the left side presented no tubercles or caseous areas. Of course, it would have been in any case a suggestive fact that at the apex of the right lung there was an area of caseation and softening the size of a walnut, but I repeat again, as it is a point of importance, that without the most careful scrutiny the nature of the extensive, chronic pleurisy on the left side might have been overlooked. The second point of interest is the fact, well shown in the case just mentioned, and also in the case of John P., that a chronic tuberculous pleurisy may exist for a long time, and lead to great thickening without any extension of the fibroid process into the lung itself.

(3) And lastly, in some instances, the fibroid processes in the pleura may invade the lung tissue and lead to extensive sclerosis. In only one instance out of the 32 instances of tuberculous pleurisy was there any evidence of direct involvement of the lung.

Case XIII. Chronic tuberculous pleurisy; interstitial pneumonia.

Wm. S., aged sixty, admitted November 1, 1890. The patient is a large, strongly built man; states that his family history is good; denies syphilis; has used alcohol to excess; had typhoid fever five years ago; rheumatism six years ago. He came in complaining of shortness of breath and cough, which symptoms he has had since the spring of the present year. He states also that he has lost very much in flesh. Has had no diarrhœa; no hæmoptysis, and does not think that he has had much fever.

Though a large-framed man he is somewhat emaciated, and is anæmic. Pulse is 100; respiration 36. Chest is broad, of good depth; costal angle 90. There is deficient expansion on the left side; no definite dulness at the apices or axillæ; at the left base the note is high-pitched. The breath sounds are enfeebled in front; expiration slightly prolonged; a few dry râles heard occasionally. There is a friction sound in the lower left axilla. At the left apex the breathing is puerile in type, with fine crackling râles. Many tubercle bacilli were found in the sputa. The case was regarded as one of senile tuberculosis, with some emphysema. He had repeated attacks of shortness of breath, and on the morning of the 9th he had a very severe attack, with small, rapid pulse, and died apparently in syncope. The temperature was very irregular, frequently sub-normal, as low as 96°, and on several occasions 95°.

Autopsy. In right pleural cavity about 200 c. c. of cloudy fluid. The pleura is divided into many compartments by fibrous septa. Both layers are thickened, and present many miliary tubercles and tuberculous granulation tissue. Left pleural cavity is obliterated by firm adhesions. The lungs are voluminous, and they do not retract on opening the chest. There are numerous, dense bands of fibrous tissue running through them, most marked at the apices, and these bands extend directly from the pleura into the lung substance, particularly from the root. There are small areas of caseous pneumonia. The bronchi of both lungs are somewhat dilated and filled with muco-purulent contents. There is a cavity the size of a hazelnut at the apex of the right lung. The condition is that of an interstitial pneumonia, with dilated bronchi, and an extensive tuberculous pleurisy on the right side. There is a small tuberculous ulcer in the larynx.

General Serous Membrane Tuberculosis.

There is a group of cases of tuberculosis in which the serous membranes are chiefly involved, either simultaneously or more commonly one after another, forming a clinical type fairly distinctive and readily recognized. There have been several interesting studies of this condition, notably the Paris Theses of Moran and Boulland in 1884 and 1885, and the careful study of Vierordt.[2] The pleuro-peritoneal membranes may be alone involved, or the pleuro-peritoneal and pericardial surfaces. There are, as noted by Boulland, three groups of cases.

First, an acute tuberculosis, with rapid evolution of the disease in pleuræ and peritoneum, generally consecutive to local disease of the tubes in women, or of the mediastinal or bronchial lymph glands.

Second, cases in which the disease is more chronic in its nature, with exudation in both peritoneum and pleuræ, the formation of cheesy masses, and the occurrence of ulcerative and suppurative processes. In this group the pleural involvement is much more commonly secondary to the peritoneal, or both may be a sequence of pulmonary tuberculosis.

And, third, there are instances in which the pleuro-peritoneal affection is still more chronic, the tubercles hard and fibroid, both the membranes showing much thickening, often with very little exudation. My experience with this form of general involvement is not great, and of the thirty-four instances of peritoneal tuberculosis which have been under our observation at the Johns Hopkins Hospital, in only one was there involvement of the pleura.

I have not met with an instance in which the three serous surfaces were involved together, though many such are on record, and in some the disease has been almost exclusively confined to these membranes.

A knowledge of the existence of this combined infection is somewhat important, as such cases are often of great obscurity. More commonly the affection begins in the peritoneum and may be extremely chronic, and then gradually invades the pleura. In other instances there is a sub-acute pleurisy and subsequent invasion of the peritoneum. The cases often have a very protracted course; there are periods of great improvement, and there may be little or no fever. The following case is at present under observation:

Case XIV. Pleuro-peritoneal tuberculosis; an illness with anasarca; great improvement; persistence of ascites; development of right-sided pleurisy; drainage of peritoneum.

R. A. B., colored, aged thirty, farmer, admitted May 9, 1893, complaining of swelling of the abdomen. Father and mother, two brothers and one sister living. Was healthy as a boy; measles at nineteen, scarlet fever at twenty-seven, no other serious illnesses. Married ten years, wife healthy, three children. Has not had venereal disease; has been a temperate man. For two years past patient has had failing of eye sight (cataract), which, he says, is due to irritating dust.

Present illness dates from last October, when he had an attack of gradually increasing shortness of breath, with swelling of the legs and body. Evidently this was a very severe illness, as he was confined to a chair for three months, and was not able to lie down. He had no special cough, but does not know whether he had much fever. The swelling in the legs gradually disappeared, and has been absent now for about three months. The swelling in the abdomen has persisted. He complains chiefly of shortness of breath on exertion, and of the swollen abdomen. He has a little cough and slight, scanty expectoration. Patient is a medium-sized, moderately well-built man; face not specially emaciated. The temperature on admission was 97.5°; rose in the evening to 103°. He lies quietly in bed, head not elevated, no respiratory distress. The conjunctivæ are a little yellow, pupils are dilated. Mucous membranes are somewhat pale. Pulse is regular, 90 to the minute, the vessel-wall a little sclerosed. The brachials pulsate visibly. The chest is well formed; costal angle good; the lower part of the thorax is expanded. On deep inspiration, the left side moves more than the right. Percussion gives a dull note on the right side, beginning at the sixth rib in the recumbent posture, and in the erect posture at the fourth rib, the dulness being distinctly

[2] Zeitschrift für Klinsche Medecin, Bk. xi.

movable. Behind, when sitting up, the line of dulness is above the angle of the scapula. Percussion is clear throughout the left side. Tactile fremitus is diminished over the dull area on the right side, and the breath sounds are feeble. There is no friction murmur heard. Apex beat of the heart is not very distinct; pulsation in the fifth space, just inside the nipple line. The sounds are everywhere clear. A needle was inserted into the pleura and a serous, greenish-yellow fluid was withdrawn, containing a little blood, which did not coagulate on standing. Cover-slip preparations of the serum showed no organisms, and cultures on agar remained sterile.

The abdomen is distended and large, but symmetrical in the flanks and a little prominent in the umbilical and epigastric regions. On palpation it is everywhere soft, painless, not resistant, except in the upper zone, a little above the level of the navel. In the whole of this region up to the xiphoid cartilage and the costal margin, there is an ill-defined, doughy resistance, which terminates below in a tolerably well-defined border. On three separate occasions a very definite friction murmur was felt. The edge of the liver is not palpable on deep inspiration, nor can the margin of the spleen be felt. On percussion, there is tympany in the hypogastric and umbilical region, slight dulness in either flank, which is movable; no distinct fluctuation wave. There is a flat tympany in the epigastric and hypochondriac regions. The liver dulness begins at the border of the sixth rib, and extends to the costal margin in the nipple line. There are no glandular enlargements; no œdema of the feet. The urine is clear, faint trace of albumin, and a few leucocytes, and a few red blood-corpuscles. The temperature during the first week of admission was irregular, ranging usually between 98° and 100°, but on three occasions rose to 103° in the evening. Frequently the morning temperature was very low. After May 16th his temperature did not go above 100°. He has gained in weight, and the small amount of sputum which has been obtained has always been negative.

A diagnosis of pleuro-peritoneal tuberculosis was made, and on the 10th Dr. J. T. M. Finney made an exploratory operation in order to drain the peritoneum. A quantity of dark, reddish-brown liquid was removed. The peritoneum was deeply injected, and the visceral layers studded with numerous gray and yellow-gray nodular tubercles. The omentum was rolled up, and there was great thickening about the stomach and colon.

It is not very uncommon to see the pleura and peritoneum involved secondarily in chronic disease of the lungs.

(To be continued.)

MEDICAL PRACTICE IN COLORADO. — Hereafter, the Colorado State Board of Medical Examiners will recognize, as entitling their holders to a license, diplomas from such medical schools only as require three years study of at least twenty weeks each year. The school must have required a preliminary examination and given instruction in anatomy, physiology, chemistry, pathology, therapeutics, obstetrics and gynecology, surgery, theory and practice, and hygiene. In default of a diploma from such a school the candidate must pass an examination in the above subjects.

PHAGOCYTOSIS.[1]

BY HAROLD C. ERNST, M.D.

(Concluded from No. 4, page 89.)

THIS work of Christmas-Dureinck-Holmfeld is a fair example of the arguments brought forward by the opponents of the theory that phagocytosis plays any important part in the production of immunity, even if it is somewhat old; and it is of interest to see in what way Metschnikoff meets the objections, which he does in a paper written shortly afterwards.[8] He says here, that his critic is wrong in the assertion that there were few results obtained by experiments upon warm-blooded animals, as can be easily seen by a reference to his article "Ueber den Kampf der Zellen gegen Erysipelkokken,"[9] with which his opponent is not familiar, and further in the article upon "die Abschwachung der Milzbrand-bacillen im Blute immuner Schafe,"[10] in which he (Metschnikoff) uses the occurrence of phagocytosis as a prognostic sign; when many cells containing bacilli are found, the animal may be considered likely to live, when few are present (or none) death is likely to occur. He says also, that he has worked so often with rabbits, and has got such positive results, that he cannot accept those of his critic, and suggests that perhaps these latter were due to the technique employed; which is not fully described. He says that *fresh* preparations must be used, to which have been added some old Vesuvin solution, or distilled water, as suggested by Koch.[11] If this be done, there will be invariably found, in animals immune either by nature or artificially, many phagocytes containing bacilli. Metschnikoff says further, that he has many times used rats for experiment, and always with the same results as above (except that the distinction is not so sharp), and that he has also used preparations (dried only, however,) from his own blood, for the study of the struggle between the leucocytes and bacteria. He says that the observations of the behavior of bacteria in pus contained in capillary tubes, are not trustworthy,[12] even if the tubes be kept at 37° C., for they are not under natural conditions; and it is also the fact that the bacteria observed by him under these conditions produced no spores, even after three days.

From what we know of Metschnikoff's work, it is but natural to suppose that he does not agree with the objection to the experiments upon cold-blooded animals, on the ground that the results cannot be applied by analogy to warm-blooded animals; for it is just this point upon which he is most insistent. Neither does he agree with the theoretical objections and explanations that the bacteria are destroyed by the absence of oxygen, which fall to the ground since the particular bacteria under consideration are facultatively anaërobic. He goes on to say, that he has never, as is asserted, defined phagocytosis as "a power of the leucocytes of certain animals to eat the invading bacteria (and so destroy them)," any more than he has ever asserted that "every organism is immune to such parasitic dis-

eases, the parasites of which, the phagocytes of such organism can destroy" — anybody who will take the trouble to read his assertions will see that this is not so. The assertion that "most suppurative bacteria are never enclosed by the leucocytes" is not true, as is shown by many observers; and, in point of fact, the enclosing of bacteria by the leucocytes was first demonstrated in the suppurative bacteria. When the assertion is made that the fluid of pus itself can destroy bacteria, by depriving them of oxygen, how is the retention of its vitality and pathogenic properties by the bacillus of tuberculosis explained, an organism that is extremely aërobic, and requires so much oxygen for its continued vitality? He closes by saying that while he certainly has difficulty in explaining certain diseases by means of phagocytosis, — such as erysipelas, relapsing fever, as well as mouse-septicæmia and tuberculosis, — very certainly he finds nothing in anything of them diametrically opposed to the theory. He has had the greatest difficulty with chicken-cholera; but, in his later work he seems to have surmounted much of it.

Baumgarten's opposition has probably done as much as that of any individual to destroy the influence of Metschnikoff's work. Giving the results of experiments in his own laboratory,[13] he says that they are in wide opposition to the claims of Metschnikoff upon the importance of the leucocytes in producing immunity against, or the healing of bacterial processes. If anthrax spores or bacilli be injected into the dorsal lymph-sack, some of the elements are, after a time, taken up by the leucocytes; *but*, the degeneration and disappearance of the bacilli occur *first* among those in the lymph-fluid, *later* in those contained in the cells. On the contrary, in frogs kept at 25°–30° C., an *increase* of the englobed bacilli may be found, but the frogs die with a great increase of the bacilli in the blood and organs (as of course would be the case, if the phagocytic action had not been sufficient to arrest their development). In pigeons immune to anthrax (and not all of them are so immune) the injected bacilli have disappeared, at the latest, in twelve hours, without the slightest perceptible entrance of any of them into the cells (several of the lantern slides will show that this is not so), and even without the slightest *microscopic* appearance of suppuration; observation of the disappearance of bacilli in distilled water shows that it occurs in the same way, as Baumgarten thinks, by the absence of nutrient material. The process of healing of the cornea after staphylococcus infection seems to show that the leucocytes die *before* the cocci (?), so that they can have nothing to do with the destruction of the cocci.

Again[14] he criticises Metschnikoff's work very severely, saying that it can be concluded, from his own (Metschnikoff's) observations, that phagocytosis was not the healing agent; that in rothlauf, healing occurs without any phagocytic action; that warmed frogs would die any way, without the injection of anthrax bacilli; that in cold frogs there is never a complete attack of the bacilli by the leucocytes, and that these cannot therefore be the curative agent (?); that the same thing is to be said in regard to recurrent fever in apes. His criticism is ironical; and he concludes by saying, that the results of his own and his assistant's work are diametrically opposed to those of Metschnikoff.

[14] Zeit. f. klin. Med., xv., s. 1.

Metschnikoff[15] reviews the work of Fahrenholz[16] and Czaplewski[17] with especial care, because they form the basis of Baumgarten's criticisms upon phagocytosis. Fahrenholz's conclusions (working with the spores of anthrax) are exactly the opposite of those of Metschnikoff; and the latter in turn shows that the experiments of Fahrenholz of keeping frogs at a temperature of 25°–27° C. were exceedingly crude and unsuccessful, and cannot be taken as evidence. Not only was the temperature faulty, but the spores themselves were of poor quality (p. 37), he having used those that were six years old. Metschnikoff remarks that the wonder was that any results in keeping with his own were obtained with such material; and then says, that, if the experiments had been made in accordance with proper regulations, the results would doubtless have been the same as those of Lubarsch[18] which are in complete accord. Czaplewski rejects phagocytosis, and the "chemical" theory as well, as explaining the immunity of pigeons against anthrax, and frankly confesses that he does not know how it occurs. Whereupon Metschnikoff refers him to Hess[19] and Nuttall[20] on the one hand, and on the other declares that the immunity of pigeons, in this affection, is one of the very best examples of macrophagocytosis; these macrophagocytes being the large mononuclear cells, easily staining with the aniline colors, and occurring so abundantly that Czaplewski must have seen them, but failed to recognize them — probably meaning them by the term "little masses in which the bacilli are crowded together," the occurrence of which he notes as common. They were probably poorly stained; for which reason, Czaplewski did not recognize the nucleus.

Baumgarten makes himself responsible for these two articles;[21] and in the same place from which we have been extracting, Metschnikoff shows that Baumgarten makes statements differing from the original ones of Fahrenholz.

To take another instance: Finger[22] concludes, from the varying behavior of glanders bacilli in susceptible, immune, and immunized animals — their growth in the tissue fluids, their death in other situations, the appearance of leucocytes in immunized and susceptible animals, and their complete absence in immune animals — that we have to do with a complicated process, and that, not only the leucocytes, but the tissue fluid itself, has a great part to play in these processes; facts with which Metschnikoff's theory cannot well be brought into harmony. Which would be very true if that theory claimed all that the critic ascribes to it; but Metschnikoff[23] says that, "among the biological causes [of immunity] are to be mentioned cellular action in general, and especially the microbicidal action of the phagocytes . . . the most difficult point in the study, being to separate the different agents that can assist in producing immunity," showing distinctly that he does not ascribe it all phagocytosis.

Bitter[24] gives a long review of all the work done up to that date upon phagocytosis, including Hess,[25] Rib-

bet,[26] Lubarsch[27] and Pawlowsky,[28] in favor of Metschnikoff's arguments; and Baumgarten,[29] Weigert[30] Christmas - Durckinck - Holmfeld[31] and Emmerich[32] against his conclusions. Upon the basis of this review and the work of Nuttall[33] he concludes as follows: "Nowhere do we find in Metschnikoff's work, or in that of his supporters, *absolute proof* that phagocytes take up and destroy vigorous disease-producers that are dangerous to the body. Against this conclusion are the new observations upon the intensive degeneration of virulent bacilli in the body-fluids without the help of the cells; the late taking up of the injected bacilli by the cells; the greater taking up, and with increased readiness, of the injected cultures in complex cases; and, finally, the appearance and activity of the phagocytes, especially at such a time and in such a condition of the body, that the attack of the infectious element and the pressing need of the body is over; further, he considers that the phagocytes employ their "eating" power only against bacteria that have lost some of their vital energy. He does not deny that phagocytosis *may* occur in accordance with the hypothesis of Metschnikoff, but he does not consider that its general applicability (validity) is established. If it is desired to prove this, it must be demonstrated, without doubt, that phagocytosis occurs at once upon the entrance of living and fully virulent bacilli, and that an effective destruction of them does not occur without the intervention of the cells. That phagocytosis does occur as soon as it may be reasonably supposed that the cells can exercise their function may be seen in some of the slides to be shown; but neither Metschnikoff or any one else would attempt to claim that this is *all* that is necessary for the resistance of the organism to an attack in all cases.

Wolfheim[34] experimenting with the staphylococcus aureus, and producing keratitis with it in the rabbit, found many more cocci between than in the cells, and that, after from two to six days, the phagocytes showed more or less signs of degeneration. Therefore, the phagocytes can in no way act *alone* as the destroyers of the bacteria.

Buchner[35] seeks to oppose phagocytosis by asserting that the leucocytes are attracted solely by substances extracted from the bodies of bacteria, and that, as a consequence, the bacteria must have been already destroyed by the bactericidal properties of the body-fluids, before the leucocytes proceed towards the invaded region. Such a supposition is opposed by these facts: (1) leucocytosis in infectious diseases is observed from the beginning, that is to say, when the bacteria are living; (2) the increase of the leucocytosis is seen to occur along with the rise of temperature, and ceases exactly at the "crisis," just when a large number of bacteria perish; (3) leucocytosis is seen in cases in which bacteria are living in the blood, as in the anthrax of susceptible animals and in the recurrent fever of man; (4) the leucocytes, as Buchner himself acknowledges, englobe living bacteria — when the bodies of the bacteria are very numerous, but associated with toxic products, the leucocytes, instead of being attracted, are repelled by these toxines.

Emmerich[37] goes much further than Behring, asserting that phagocytosis has *nothing* to do with immunity. Metschnikoff shows that his experiments were fallacious, when he asserted that the bacteria of "Rouget" were completely destroyed in twenty-five minutes, a time too short for phagocytosis to occur, for Metschnikoff could not, and Emmerich has not since been able to, show the complete destruction of the bacilli in less time than a number of hours, which is plenty of time for the leucocytes to arrive at the threatened point and to exercise their phagocytic property.

Among the mass of papers that have been written upon the subject it is a relief to find the following conclusions by Lubarsch:[37] (1) It appears as yet to be impossible to give a general explanation of immunity, even for a single bacterial disease; (2) for certain cases, it appears extremely probable that immunity is produced by a reciprocal action between the cells and the bacteria, which, as I suppose in opposition to Metschnikoff, has its results outside of the cells; (3) a bacterial-destroying property of the circulating blood *independent of the body cells* is, as yet, unproven.

Ruffer[38] has made a series of investigations "On the Phagocytes of the Alimentary Canal," and formulates his conclusions as follows: first remarking that it is interesting to note that the phagocytic phenomena seen in the intestines occur most commonly in, and in the neighborhood of, Peyer's patches, the seat of so many of the diseases occurring in them; (1) migratory cells possess the power of passing to the surface (of the intestine); (2) there are two sorts of these cells, the *micro* and the *macro* phagocytes; (3) the latter produce also microphagocytes; (4) the macrophagocytes possess the power of destroying microphagocytes; (5) both destroy bacteria; (6) in the normal mucous membrane, the bacteria never occur free between the cells in the lymph or blood channels; (7) the destruction of the bacteria constantly going on in the lymphatic tissue of the intestines has the greatest similarity to the destruction of pathogenic bacteria in resisting animals.

Metschnikoff[39] has shown the very interesting fact, that phagocytic intracellular digestion goes on in certain cases in an acid medium, although, in other instances in the same experiment, no reaction makes itself apparent. In some of the macrophagocytes seen in his experiments, there was to be seen, near a red granule of litmus, a vacuole containing blue granules of the same substance, showing that the production of the acid intracellular material may be limited to one special portion of the cell.

Time might be taken up almost indefinitely by reviewing articles for and against the assertions of Metschnikoff, but this would be useless. Perhaps the best method for bringing this part of the discussion to a close will be to quote from his book upon "Inflammation," his answer to one of the most prominent objections to his theory. He says (p. 230 et seq):

"But, they say — and this objection has been made

many times — if phagocytic reaction is developed in order to protect the organism against danger, how is it, that just when the organism is the most menaced, the phagocytes refuse to carry out their part? Here, also, the objection comes from an incomplete knowledge of the principles of the theory. Just because the defence by the phagocytes is developed in accordance with the law of natural selection, and not following out a predestined purpose, it is perfectly natural that cases should occur in which the phagocytes do not accomplish their function, which threatens great danger and death to the organism. In nature, there are found varying characters, sometimes useful, sometimes hurtful to the organism. The first produce survival, the second death. If, for example, we consider two organisms — the one, the phagocytes of which are easily repelled by the bacterium; and the other, whose phagocytes manifest a positive sensibility, bringing on an abundant phagocytosis — the first will easily become the prey of the parasite, will be eliminated by natural selection; whilst the second will resist the infection, will survive, and will produce successors endowed with the same phagocytic powers. It is evident that in such conditions, the activity of the phagocytes will augment, supported by selection.

"But the curative force of nature, of which inflammatory reaction is the most important element, has not yet reached a perfect adaptation. The frequency of disease and of premature death proves this quite sufficiently. The phagocytic property has not yet reached its last stage of development, and is still undergoing perfection. Often the phagocytes retreat from the enemy or destroy the elements of the organism of which they form a part (as in the scleroses). It is this imperfection that has for so long rendered necessary the intervention of man — not satisfied with the action of his natural curative force. . . . But if on the one hand, medical science has so much that should rest upon biology, of which it constitutes but a part, this service should not be gratuitous.

"General biology itself can gain great advantages by including morbid phenomena in its studies. Often biology finds difficulties in its study of the processes of evolution, because these phenomena are presented under a completed form. So that, for the close analysis of natural selection, the too well-balanced phenomena occurring in nature do not furnish favorable material. To shed light upon this general law, less stable phenomena must be studied — in short the actions less completed, in which the action of natural selection can be observed from day to day. Such are precisely to be found in morbid phenomena with the reactions which they excite — the struggle between the organism and its aggressors, which gives the best opportunity for a consecutive study of the progress of natural selection. In this struggle there always occur survivals, the result of selection, and deaths, occurring for the same reason. On the one hand there are the victorious organisms selected and the parasites destroyed; on the other, the vanquished organisms are eliminated and the conquering parasites selected."

I have endeavored to give, as briefly as possible, a selection of the main arguments against the theory that phagocytosis plays an important part in many of the processes resulting from the attack of the living organism by infectious bacteria, together with some of the replies that may be made to these criticisms. I have also endeavored to show that it is not possible to ignore all the facts that have been brought forward in favor of such a view, as well as to do away with the common impression that the theory is urged to the exclusion of any of the other phenomena that undoubtedly occur. Personally, I am constrained to believe that it is a force that is always present and ready to act, although under many conditions its action is of the slightest, and practically imperceptible by the rough means of observation at our command.

There are, of course, many gaps to be filled in the chain of evidence, but there seems to be no one more ready to acknowledge this than the original author of the theory himself; and certainly no one has, of late years, shown as much brilliancy and persistency in carrying out the investigations necessary to establish his point.

LEUKOCYTOSIS AS AN ELEMENT IN THE PROGNOSIS OF PNEUMONIA.

BY RICHARD C. CABOT, M.D.,
Medical Interne, Massachusetts General Hospital.

In view of the conclusions reached by Uskow, Kilodse, W. S. Thayer and others, on the prognostic importance of leukocytosis in pneumonia, the blood of forty-nine cases of well-marked croupous pneumonia occurring at the Massachusetts General Hospital since February 1, 1893, has been examined in dried cover-glass preparations. These cases occurred in the services of Drs. E. N. Whittier, W. L. Richardson, R. H. Fitz and F. C. Shattuck, to whose kindness I am indebted for permission to report the results:

Leukocytosis was present in 41 cases, of whom 10 died.

Leukocytosis was absent in 5 cases, of whom *all died.*

Leukocytosis was doubtful in 3 cases, of whom 1 died.

In order that the influence of personal equation might be as nearly as possible the same in all cases, an exactly identical technique was used in all.

A small drop of blood flowing freely from a prick in the ear, was touched with the centre of a carefully cleaned cover-glass. This glass was then quickly dropped with the wet side against another glass, and the two slid apart before they had time to stick. The layer of blood on the dried glasses is, after a certain number of trials, approximately of the same thickness in each case, if the observer use always the same technique. In the writer's experiments the field of a Leitz No. V objective with a No. 3 eye-piece focused on the centre of a cover-glass so prepared, contains from 500 to 1,000 red corpuscles. This has been verified by repeated counts. Such a field, if the blood were normal, would contain one to three leukocytes. In the pneumonia cases examined, there were in a large majority of the cases from five to ten leukocytes in such a field; one case was counted, and showed a proportion of one white to fifty-four red.

In the five cases above mentioned, in which no leukocytosis was found, the examination was repeated several times at different hours of the day, but the results were always the same.

As far as these figures go, therefore, it would seem that while the presence of leukocytosis is not a very hopeful sign (one-fourth of those in whose blood it

was present having died), *its absence makes the outlook bad.* Moreover, in two of these five cases the other reasons for giving a bad or guarded prognosis were not present. The individuals were both under fifty, were not at all alcoholic or weakly, and there was nothing in the condition of pulse, temperature, nor in the physical signs in the chest, to lead one to expect a fatal result. Yet both went down with surprising rapidity, and without any reaction to vigorous stimulation and supportive treatment.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY CHARLES M. GREEN, M.D., BOSTON.

IMPREGNATION DURING THE PUERPERIUM.

KRONIG,[1] at a meeting of the Obstetrical Society of Leipzig, March 20, 1893, reported the following case: The patient, twenty-two years old, healthy, had always menstruated regularly every four weeks. The birth of her first child took place July 4, 1892: the child was suckled by the mother for ten days, and throve. On the eighth of July, four days post partum, coitus took place, followed by sexual abstinence for three months: the menstrual periods did not appear. Fœtal motion was first felt in November, 1892, and the child was born March 10, 1893, 243 days from the date of coitus, and 247 days from the birth of the last preceding child. The infant bore every appearance of maturity, although, of course, it was premature by 27 days: it was 20.8 inches long, and weighed over 7.5 pounds.

From this case Krönig draws the following conclusions:

(1) During a pregnancy of 243 days, reckoned from the fertile coitus, a mature child can be developed. [This amounts simply to saying that an eight months infant usually *appears* mature, a statement which no one can gainsay. — REP.]

(2) Spermatozoa retain [that is, may retain] their vitality in the lochial secretion.

(3) Ovarian activity does not entirely cease during pregnancy; the follicles ripen so that they may reach maturity very soon post partum.

(4) Menstruation and ovulation may occur independently of each other.

(5) In strong and healthy persons in the puerperium the endometrium may rapidly reach such a degree of regeneration that it is possible for the impregnated ovum to obtain a nidus very early in the convalescence.

In the discussion Rösger remarked that he had seen in the dead subject, as early as two days post partum, glandular crypts in which an ovum could take root. The customary representation of the puerperal endometrium as a wound-surface holds good only for the placental site. Rösger cited, as a curiosity, a case of coitus intra partum.

THE MANAGEMENT OF BREECH PRESENTATIONS.

Etienne[2] (Nancy) reports a series of fifty breech labors, with viable fœtuses, with no infantile mortality, — a remarkable result, considering the usually accepted mortality of ten per cent., or even of 25 to 33 per cent. (Hegar) in primiparous cases. Etienne's cases were conducted in the Nancy Lying-in Hospital between 1883 and 1891: there were 76 cases in all; but 26 were rejected in which the fœtus was either dead ante partum or non-viable.

The secret of the success in the Nancy Clinic is a skilfully exerted suprapubic pressure during the extraction, whereby the extension of the head and the slipping up of the arms are prevented. [This is no new manœuvre: it has long been taught in the best schools, and its importance is occasionally emphasized in journal articles. It is probable that the usual mortality, while partly due to a general want of obstetric skill, is almost entirely attributable to the want of intelligently applied vis a tergo while the operator is making tractions on the child's legs and trunk. Unquestionably, well directed pressure in the proper axis on the fundus uteri through the abdominal walls will almost invariably prevent the extension of the head and the upward displacement of the arms; and consequently it should be an invariable rule of practice that the obstetrician should have with him, during the second stage of breech cases, a skilled assistant. It is not enough to send for assistance after the arrest of the head has taken place, for then it is too late. We are confident that if the above rule is conscientiously followed the fœtal prognosis in breech cases will be greatly improved. — REP.]

CEPHALIC VERSION IN PRESENTATIONS OF THE BREECH.

Owing to the greater fœtal mortality in breech labor, this mortality being about ten per cent. as compared with two per cent. in head presentations, many teachers of obstetrics, especially of the French school, have recommended that cephalic version be performed by the external method, before rupture of the membranes. The wisdom of this procedure as a rule of practice has been questioned by teachers in this country, owing to risks of prolapse of the funis or of the fœtal extremities, or again of entanglement of the cord and interference with the fœtal circulation. Now, no less an authority than Tarnier[3] reports a case as a warning against cephalic version in most cases of breech presentation. A patient had been admitted to hospital with a breech presentation, and a foot not being within reach Tarnier decided to perform cephalic version by the external method: this was done; but subsequent vaginal examination showed that a hand had prolapsed, and a little later the cord also prolapsed, and meanwhile the membranes ruptured. Tarnier admitted that it would have been better not to turn the child.

THE INFLUENCE OF CHLOROFORM UPON THE COURSE OF NORMAL LABOR.

Dönhoff[4] gave chloroform to various degrees in five cases of normal labor, and observed its influence upon the expulsive forces (uterine and abdominal muscles), as shown by the tachadynamometer. His conclusions follow:

"(1) The administration of chloroform, even in diminutive doses, exercises a retarding influence upon the progress of labor. The muscular pressure sinks

[1] Centralblatt für Gynäkologie, No. 19, 1893.
[2] Arch. de Tocol. et de Gynæc., May, 1893; British Med. Jour., June 3, 1893.
[3] Journ. des Sages Femmes, November 16, 1892; British Med. Journ., December 17, 1892.
[4] Archiv für Gynäkologie, xlii, 2; Amer. Jour. of Obstetrics, June 1, 1893.

to one-half of the amount of that present before the administration of the anæsthetic. In eight observations the average figures were as 13 : 7.

"(2) The expulsive force of the uterine contractions steadily diminishes during the exhibition of chloroform.

"(3) The labor pains, besides being weaker, are also more irregular during a slight anæsthesia. During deep anæsthesia the intervals between the pains are longer, and all the pains are diminished in strength.

"(4) The pains increase immediately after discontinuing the anæsthetic. The expulsive force of the contractions after stopping the chloroform, compared with the force just before its administration, is, as expressed in figures, 2 : 3.

"(5) The labor pains generally continue diminished in power for some time after discontinuing the chloroform. In one case they had resumed their normal intensity in ten minutes, while in two other cases two hours had expired.

"(6) If the action of the abdominal muscles is only slight, this action is checked entirely by a superficial anæsthesia, but soon reappears after the stopping of the chloroform.

"(7) The action of the abdominal muscles continues, but in diminished force, during superficial anæsthesia, if before the exhibition of the chloroform it was vigorous in character.

"(8) Deep anæsthesia abolishes entirely the action of the voluntary muscles.

"(9) The intervals between the pains become longer immediately after chloroform is administered, and the labor pains, besides being less intense, decrease in numbers about 25%.

"These experiments show that chloroform, no matter in what degree it is administered, exercises a retarding influence upon the progress of labor. The expulsive forces are lessened, and there is no corresponding diminution of the resistance."

INVOLUTION OF THE PUERPERAL UTERUS.

Ries [5] has studied this subject clinically and anatomically, dividing the work into two parts, of which the first deals with the question "How long does the internal os uteri remain patent?" while the second discusses the involution of the placental site, clinically considered. He bases his conclusions on an examination of 46 puerperæ from the fifth to the sixteenth day of convalescence. There appears to be no actual distinction between primiparæ and multiparæ in respect to the completion of os closure. The earliest day on which the inner os was no longer open, Ries found to be the eighth. When the lochial discharge is very profuse, the os is found to close less soon than when the discharge is scanty. On the other hand, the earlier the fundus sinks to the brim, the more surely one expects to find the os closed. After premature labor, and especially after abortion, the os closes earlier than after full-term labor.

The placental site was generally found near the inner os, and about the size of a saucer. Its surface was either only somewhat uneven and rough, or one found firm, roundish, projecting humps, which could not be separated by forcible pressure with the fingertip; or, finally, these humps were covered with soft masses, which in some cases had spread, fungus-like, over the whole placental site. These humps are thrombi in the venous sinuses: by their varying degree of firmness one can discriminate between old and fresh thrombi. The soft covering is formed by the blood flowing over and coagulating on the thrombi from unclosed vessels at the time of placental separation. The humps and their covering, so far as they do not become organized, disappear partly as ingredients of the lochial discharge, partly they are cast off as small clots, and finally a part is discharged only at the next succeeding menstruation. It cannot be said with certainty just when the placental site is completely restored to the condition of the rest of the endometrium.

THE INFLUENCE OF TREATMENT OF A SYPHILITIC MOTHER, ESPECIALLY DURING PREGNANCY, UPON THE HEALTH OF THE INFANT.

Etienne [6] draws the following conclusions from the study of thirty-two cases of pregnancy in syphilitic women:

"(1) The fœtal mortality, in cases in which the mother has never been treated, is enormous, reaching 95.5 per cent. If treatment be applied throughout pregnancy, we may hope to obtain almost complete immunity from this infant mortality.

"(2) Syphilis attacks the fœtus especially during the fifth, sixth, and seventh months of intrauterine pregnancy.

"(3) Paternal syphilis is less injurious to the fœtus than maternal syphilis.

"(4) The prognosis differs according to the stage of pregnancy when the mother becomes contaminated.

"(*a*) If infection occurs during the first three months, and is not treated, the mortality during the first few days after delivery reaches one hundred per cent.

"(*b*) The prognosis is a trifle better, if infection occurs during the fourth and fifth months.

"(*c*) In one case of infection at the eighth month, the child lived and was apparently healthy; in a second similar case the child was in good condition at birth, but developed symptoms of syphilis later.

"(*d*) Whenever suitable treatment was administered, the mortality was *nil*.

"(5) In no case were any unfavorable results met with from internal medication during pregnancy."

RECENT LITERATURE OF PUERPERAL ECLAMPSIA.[7]

(1) Gerdes reports the results of a number of bacteriological investigations made by himself, with cultures from the blood, lungs, liver and kidneys of two women who died from eclampsia. Keeping these cultures in an incubator for twenty-four hours, he found colonies of bacteria resembling the bacillus of chicken cholera. Inoculations with pure cultures produced in mice convulsions, coma, and death: and he concludes that "Puerperal eclampsia is produced by a specific microorganism found in the blood and various tissues of women suffering from this disease."

(2) Hofmeister experimented with cultures obtained from Gerdes, and believes that Gerdes's eclampsia bacillus is nothing but the bacterium of putrefaction.

(3) Haegler subjected three cases of well-marked eclampsia to a number of bacteriological experiments; but his results were not in accordance with those obtained by Gerdes, and he does not believe in the bacteriological origin of eclampsia.

[6] Annales de Gyn., April, 1892: American Jour. of Obstetrics, February, 1893.

[7] American Journal of Obstetrics, March, 1893.

(4) Fehling considers the theories of Gerdes, Doléris and others as unproven and improbable. He says that in four hundred cases of eclampsia, observed by Olshausen, Dührssen, and Gusserow, albuminuria was present in ninety-eight per cent.; and that we do not need bacteriological theories to explain the etiology of puerperal eclampsia.

(5) Döderlein made bacteriological investigations in eight cases of eclampsia, subjecting the blood, urine and various tissues to a number of experiments, all of which resulted negatively. He agrees with Haegler and Hofmeister, and concludes that the Gerdes bacillus is not the cause of puerperal eclampsia.

(6) Dührssen has written an important article on this subject. He considers that blood intoxication is the most frequent cause of puerperal eclampsia, the toxic agents being kreatin and kreatinin, the elimination of which is prevented or diminished by a simple nephritis of pregnancy, by chronic nephritis, hydronephrosis, hyperæmia of the kidneys, and through a retention of urine caused by pressure upon the ureters. The kreatin and kreatinin are deposited in the cortex of the brain, and excite certain motor centres capable of producing convulsions and coma. Excitability of the nervous system, especially of the nerves of the genital organs, and strong emotional disturbances, add to the irritation produced by the altered condition of the blood. Rarely a hyperæsthetic nervous system may in itself produce a reflex eclampsia.

[The weight of authority, therefore, discards a microbic origin of eclampsia, and for the present, certainly, the theory of renal insufficiency with central toxæmia holds good.—REP.]

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

REGULAR meeting, April 8, 1893, the President, DR. CHARLES M. GREEN, in the chair.

DR. F. B. HARRINGTON, for the Committee, read resolutions on the death of Dr. C. P. Strong, which were published April 13th, in the *Boston Medical and Surgical Journal.*

An account of Dr. Strong's last illness and the post-mortem results were given by Drs. F. B. Harrington, W. F. Whitney and A. K. Stone.

DR. ABBOT said that the lamentable death of our beloved associate brought very forcibly to one's mind the question whether it is possible for a septic fluid to be absorbed by the skin without any lesion of the surface. Such occurrences, he thought, must be extremely rare, but he could testify from personal experience to their possibility.

Some years since, after making at the Massachusetts General Hospital an autopsy in a case of double empyema, in which he removed the lungs without protecting his hands in any way, he was taken within a few hours with severe chilliness and a feeling of general *malaise*, which were followed at once by an eruption on both hands of a general dermatitis, which appeared in the form of bright red, swollen patches, from an inch to an inch and a half in length, and half an inch to an inch in breadth, mostly on the dorsal surface, accompanied by a general uncomfortable sensation of fulness rather than pain, and much swelling of the fingers and thumbs, especially of the left hand. He remembered particularly that the left thumb was at least a quarter larger than natural. The symptoms, both general and local, passed off in two or three days without special treatment, except cooling lotions. The septic poisoning in this case could only be explained by a general penetration of the skin, as there was no lesion anywhere. As to the question whether such an absorption could have taken place merely by the way of the ducts of the glands of the skin without penetration of the epidermis, Dr. Abbot inquired whether Professor Whitney could give the Society any fresh information on the mooted question of the possibility of fluids passing through this membrane.

DR. W. F. WHITNEY said that there was no doubt but that chemical products of bacterial life could be absorbed through the unbroken skin, producing symptoms of septicæmia. This had been done experimentally in animals. As to the absorption of bacteria themselves through the unbroken skin, this is doubtful, although they may get into the sweat glands and hair follicles, and from these gain an entrance into the system.

DR. J. C. WARREN reported

A CASE OF DIFFUSE HYPERTROPHY OF THE BREASTS.

M. C. G., twenty-three years of age, was born in Newburyport. Her father and mother died of phthisis. Her general health has always been good. She was confined three years ago with her first child. The labor was normal and she made a good recovery.

Her breasts have always been large. At the time of entering the hospital she was six months advanced in pregnancy. During the past month the fœtal movements have been distinct. The breast began to enlarge six weeks before a lump made its appearance first in the right breast after which there was a general enlargement of the whole breast. This was followed by the same growth in the left breast. Both axillæ were occupied by soft, almost fluctuating, swellings, but there is no redness, or other symptom of inflammation. The left breast measured twenty-seven inches in circumference; the right twenty-six inches. The areolæ are large and deeply pigmented. The patient appeared to suffer no pain or inconvenience from the growth. According to Billroth these tumors consist of fibrous tissue principally. They belong to the class of growths sometimes called cysto-sarcoma. The hypertrophy usually begins at the time of puberty or a year or two later. The growth takes place rapidly and is completed within two to four months. In one of the cases reported by Billroth the growth began again at the time of puberty.

In the case recently reported by Dr. Porter,[1] the largest breast measured thirty-eight inches in circumference and the smaller twenty-eight inches. The microscopical examination by Dr. Whitney showed the growth to be diffuse intra-canalicular fibroma; therefore, not a true hypertrophy of the breast. Dr. Porter reports sixteen cases operated upon with only one death. The operation was amputation in all cases. Barton has collected in all thirty-four cases of this affection.

Since this report was made the patient has been confined, and the breasts have, according to Dr. W. F. Anthony of Bradford, diminished in size.

[1] Boston Medical and Surgical Journal, March 3, 1892.

A CASE OF CONGENITAL HERNIA OF THE LIVER.

The mother was married five years ago. Her first child was born three years ago, but died aged four months of cholera infantum. This child was born November 14, 1892. Labor began at 6 the evening before and was completed at 10 A. M. and was normal in every respect. Dr. G. W. Nickerson, of Stoneham, who was present at the birth of the child, states that he noticed quite a tense bladder-like tumor expanding the umbilical cord at its point of insertion. The child was brought immediately to the hospital and an examination showed that there was an umbilical hernia into the covering of the umbilical cord.

An operation for its reduction was performed twenty-four hours after birth. The coverings of the cord were dissected off from the tumor with some difficulty as they were adherent at several points. It was then found that the contents of the hernia were the liver. The umbilical vein and hypogastric arteries being tied, the cord was removed and the liver pushed back with considerable difficulty through the umbilical opening. The liver was about the size of an mandarin orange. The wound was closed with six silk sutures. Union took place partly by first and partly by second intention. There has been no return of the hernia at the time of writing (April 7th) and the child is in good general condition with the exception of an eczema and a right inguinal hernia.

Dr. W. L. Richardson said there had been two cases at the Boston Lying-in Hospital of hypertrophy of the breasts, and in neither case was there any milk.

Dr. T. M. Rotch said Dr. Warren's case of hernia of the liver reminded him of a case reported in the English journals, where several abdominal organs were found in the rupture.

Dr. F. B. Harrington said that the operation in this case shows how well prolonged etherization is borne in young infants if done carefully. He had operated on an infant of two weeks for webbed fingers, ether being given continuously for two hours by Dr. Scudder. Very little ether was required, a few drops only at a time, in the way that chloroform is given to adults. The infant showed no ill effects of the prolonged etherization.

Dr. Edward Reynolds mentioned an operation for the relief of imperforate rectum he had performed on an infant of a few days, where prolonged etherization was needed, and without ill effects as far as the ether was concerned.

Dr. Rotch remarked that fifteen or twenty years ago it was often thought unsafe to give ether to infants.

Dr. J. Chadwick said that in the first volume of the Proceedings of the Gynæcological Transactions he had given the result of the dissection of five cases of umbilical hernia in infants, in some of which he believes the liver was present, as in Dr. Warren's case. In the case of the Siamese twins a portion of the liver was found together with an extensive blood circulation in the band uniting the twins.

Dr. Warren said that his case perhaps differed from others in the fact that the liver and nothing else, came out in the rupture. It was a case of wandering liver. His own experience had been that children bear etherization remarkably well.

Dr. T. M. Rotch reported orally

A CASE OF INTERNAL HYDROCEPHALUS,

in a child of four years, where recovery was complete with the exception of total blindness.

Dr. F. B. Harrington reported a case of

ECTOPIC PREGNANCY,

where he had recently removed the left Fallopian tube in which the pregnancy had taken place. Two years previously he had operated for pregnancy of the right tube.

Regular meeting, May 13, 1893, the President, Dr. Charles M. Green, in the chair.

Dr. F. W. Draper reported

A CASE OF CRIMINAL ABORTION,

that had come under his observation as medical examiner. A single woman, two months pregnant, went to an abortionist on or about the 7th of January. She grew very sick and died on the 13th of January, and Dr. Draper was called upon to make the post-mortem examination eight hours after death. There was a profound general icterus. There was a foul discharge from the vagina with diphtheritic patches about the introitus. On opening the abdomen a general diffuse, purulent peritonitis was found, with large, soft spleen and gray liver and other evidences of general septic poisoning. The os uteri was patulous and there were diphtheritic ulcerations about the os. The uterus measured four and three-quarter inches in depth. Near the os there was distinct evidence of puncturing with some sharp instrument. Higher up in the uterus was another puncture one-half an inch deep, while at the fundus was a hole with sloughing edges, through which three fingers could be easily passed. There was evidence in the uterus of pregnancy, as well as a clearly defined corpus luteum in one ovary. Death was clearly due to peritonitis, following instrumental puncture of the uterus. The abortionist was arrested and, what rarely follows in these cases, was convicted. The question arose in the course of the trial as to whether it would be possible for the patient to puncture the uterus herself. Dr. Draper had thought this impossible, as the pain would be so great as to cause the patient to desist.

In the discussion which followed, several of the members suggested that the uterus was comparatively insensible to pain, bearing curetting, for example, and even accidental puncture during that operation without suffering, so that as far as pain was concerned that would not prevent extensive puncture.

Recent Literature.

The Obstetric Examination: A Short Guide for Physicians, Students of Medicine, Midwives and Students in Midwifery. By Prof. E. Credé, M.D., and Prof. G. Leopold, M.D. Edited by J. Clifton Edgar, M.D. 8vo. pp. 16, with five cuts. New York: L. Hydel. 1893.

This little treatise is a reprint of two chapters from the fifth edition of the "Text-Book of Obstetrics for Midwives," published by the authors in 1892. It is presented in this accessible form with the commendable object of "giving the widest possible publicity to the most recent experiences concerning the prevention

of puerperal fever." The preface states that these two chapters "contain the external examination and the antiseptic regulations, which are to be regarded as new and of fundamental importance." The great and fundamental importance of these teachings no modern obstetrician of note will question; but we can hardly look upon them as new. The value and the technique of the external examination were fully taught in Vienna, to our personal knowledge, some fifteen years ago; and both Chadwick and Mundé, in this country, wrote on the subject, essentially as now, at least as long as fifteen years ago, if our memory serves. Moreover, rigid asepsis has been taught and practised in the best schools and lying-in hospitals in this country for the past eight years.

It is not to be denied, however, that the value of the external examination, as a means of restricting the necessity for frequent vaginal examinations, and thereby diminishing the opportunities for septic infection, is not as fully appreciated as it should be: nor are the rules of rigid asepsis carefully carried out by any considerable proportion of physicians who were educated more than eight or ten years ago. We welcome, therefore, this and all similar treatises which will spread the doctrine of the heterogenetic origin of puerperal infection. We cannot agree with the authors (page 15) that "it is nothing less than criminal to try to assist in the stage of dilatation by attempting to stretch the cervix with the fingers and to push back the anterior lip of the cervix." While agreeing that a normally progressing first stage should not be interfered with, we know that the above procedure in some cases is distinctly indicated, and is unattended with danger, if skilfully and aseptically performed.

As a whole, we commend the teachings of this monograph highly, and bespeak for it an extensive circulation.

A Hand-book of Local Therapeutics. By ALLEN, HARTE, HARLAN and VAN HARLINGEN. Edited by HARRISON ALLEN, M.D. Philadelphia: P. Blakiston, Son & Co. 1893.

This book describes the local action only of the more important drugs under four heads: general surgery, diseases of the skin, diseases of the ear and air passages, and diseases of the eye. The pharmaceutical and physiological action, as far as it applies to external medication, are given for each drug, and by the omission of everything pertaining to internal therapeutics, it has been possible to condense in such a way as to make a hand-book easily referred to. It will be found very useful and convenient to the general practitioner, as well as to the specialist, in one of its four departments, but it might very probably have been found of more general use if these departments had been separated, and four separate publications sold. The book is well prepared. Where the use of a drug for a particular purpose is recent, the authority is mentioned in full.

Kirke's Hand-book of Physiology. By W. MORRANT BAKER, F.R.C.S., and VINCENT DORMER HARRIS, M.D. Thirteenth edition. Philadelphia: P. Blakiston, Son & Co. 1892.

The thirteenth edition of this well-known hand-book does not need an extended notice. This edition has been thoroughly revised and somewhat enlarged It is eminently well fitted as a text-book for students or for interesting reading for the general practitioner

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 3, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

CAUSES OF LONGEVITY.

IN this age of conventions and organizations, the very aged have not been forgotten. Arrangements have been made by the editorial staff of *La Science Médicale* for a convention of old men at Paris. No one under ninety years old will be eligible, and every one offering himself for membership must show proof of the time and place of his birth. Travelling and hotel charges are to be defrayed by the management of the congress, and good medical care is promised, that the guests may undergo no improper strain or exposure. Prizes are offered, and will be presented by the presiding officer. The president is a hearty centenarian who has practised medicine at Havre for seventy years. No restrictions as to nationality are to be placed upon the delegates, but extremely old persons are not expected from countries outside of France. At the time of the last census about 200 persons were reported in France as being 100 years old and over. A considerable portion of these were residents of departments bordering along the Pyrenees.

The foregoing statement leads us to consider, briefly, some of the conditions and circumstances which are attendant upon the attainment of advanced age, as gathered from observation of our own population. By the Massachusetts State Census of 1885, it appears that there were then living in the State 1,016 persons between the ages of 90 to 94 years (inclusive), 245 were between the ages of 95 and 99 years, and 43 persons of 100 years and over. A very small portion of those living between 90 and 99 years arrive at, and pass the age of 100.

The number of patients who have died in each year, having been recorded as attaining the age of 100 and over in Massachusetts, has been about 20 annually, or about one in 100,000 population, a ratio which considerably exceeds that of France.

In the Forty-ninth Registration Report of Massachusetts (1890), the compiler presents the statistics of 203

persons who were reported as having died during the ten years (1881–1890) at the age of 100 and over. Of this number, 153 or 75.4 per cent. were females. (By the State census of 1885, the number of females living over 80 years of age was nearly double that of males.) The greater exposure of men to accidents, to weather agencies, to the constant strain of business life, to the anxiety of providing for the family, all tend to shorten the life of men. The deaths by accident among men are more than threefold greater than among women, and men commit suicide in about a threefold ratio as compared with women.

Of this number of 203 deaths of centenarians, 115 or 56.7 per cent. were of foreign birth; 184 or 90.6 per cent. were married. It should not be inferred, however, from this, that married life is necessarily conducive to longevity, since at least nine-tenths of all persons who arrive at advanced age (80 years or more) are married. Of this class, a large part are widowed; and the number of widows of 80 years and over is about three times as great as that of widowers in Massachusetts.

In scrutinizing these data more carefully, there are found to be other considerations, which have an important bearing upon the attainment of advanced life. Of these 203 persons, more than half were born in foreign countries, chiefly in Ireland and the British Provinces. Of the early history of these persons, and of the accuracy of the statements relative to their ages little can be known, since their birth registers are not readily accessible. There were, however, eighty-four centenarians who were born in the United States, and of whom we have a more definite account. Two-thirds of these were born in Massachusetts, and the remainder in other States, mostly the adjoining New England States. A considerable number of these (twenty-one) died in the same towns in which they were born; and these were not mostly cities, but such small, quiet, rural towns as Seekonk, Williamsburg, Templeton, Leicester, Halifax, Essex, Bernardston, Duxbury, Holland, etc. In each one of twenty-four other instances a centenarian was born in one town and died in an adjoining town; and in nearly all of these, each town was a small agricultural community, free from the turmoil and bustle of city life. For example: one was born in Sturbridge and died in Brimfield; another was born in Goshen and died in Chesterfield, etc. These are places remote from railway communication, and are rarely heard of, outside of each quiet circle of rural life. It does not appear that any of these centenarians were burdened with great wealth, or that many of the number were excessively poor. One only is reputed to have filled a pauper's grave at Tewksbury.

Aside from the very important and controlling influences of inheritance, of diet, and of temperate habits, the points to be learned from these few statistical data, are that longevity is promoted by a quiet, peaceful life, in a retired and rural community, where there is freedom from nervous strain, and worrying, and excessively laborious toil. The business man, with increasing cares and responsibilities, the mill-operative toiling hard to keep together the souls and bodies of himself and his family, the politicians, the hard-working professional men are not the chief contributors to the centenarian ranks. Dr. Holyoke, indeed, became a centenarian, but his example has rarely been followed by his professional brethren.

English statistics confirm some of the foregoing statements. The Registrar-Genèral stated, in 1871, that the number of persons in England who arrived at the age of 100, averaged 78 annually for the preceding ten years, and of this number 21 were men and 57 were women.

Men of science have occasionally expressed doubts as to the evidence of any human life having exceeded a century. But the testimony of town and parish records too often confirm the fact to admit of reasonable doubt. One insured life closed at the age of one hundred and three, in which all the necessary documentary evidence was produced in confirmation of the accuracy of the statement.

The conditions and environment which favor long life appear to be a long-lived ancestry, mental tranquility, sobriety, freedom from care and anxiety. It would, therefore, seem to be a hazardous undertaking to summon a congress of extremely aged people to the noise and tumult of a gay and crowded city, many of whom have probably never traveled far beyond the confines of the rural villages in which they were born.

THE MILK-SUPPLY OF BOSTON.

The annual report of the department for the inspection of milk and vinegar, shows a very satisfactory condition of the milk-supply of the city, and especially a satisfactory system of inspection by which the purity of the milk-supply is insured. Although this system of inspection has existed for several years, weak spots have been strengthened by more or less recent legislation and decisions of the courts. An important advance was obtained in the decision by the Supreme Court, that the milk laws apply to sales by hotel keepers of milk to be drunk on the premises. The inspectors found a very large proportion of samples obtained from these establishments to be of a very poor grade — skimmed, watered and colored. This poor milk was especially found in restaurants frequented by the poorer classes. Many prosecutions were undertaken against these restaurant keepers, resulting in nearly every case in a conviction, the result of which has been a very speedy improvement in the quality of the milk sold in restaurants throughout the city. A large number of dealers during the hot weather have been convicted of mixing different preservatives with the milk. These preservatives are manufactured by the wholesale and sold through the country, the contents often being unknown to the milkmen who buy them. The common preservative is a substance made of a mixture of boracic acid and borax, and its presence in milk is easily detected. An important decision has recently been

given by the Supreme Court, on the question whether cream is a form of milk, and whether the milk laws are applicable to it? The decision sustains the government in its prosecution of those who were complained of for selling poor cream.

An appendix to the report includes the laws of Massachusetts in regard to the inspection and sale of milk, and the important decisions of the Supreme Court under these laws. The decision previously mentioned in regard to cream makes it illegal to sell cream containing a foreign substance, in this case boracic acid, under the same law as applies to milk.

A person may be convicted of selling adulterated milk, although he did not know that it was adulterated. The constitutionality of the law is confirmed, providing that if the milk shall be shown upon analysis to contain more than 87 per cent. of watery fluid, or to contain less than 13 per cent. of milk solids, it shall be deemed to be adulterated. If milk, reduced below this standard by the subtraction of the cream, be offered for sale, it must be sold as skimmed milk, and not as milk. Skimmed milk must contain at least nine and three-tenths per cent. of milk solids, exclusive of fat, and the vessels containing it must be plainly marked "Skimmed Milk." In the case of skimmed milk, the defendant would be liable, unless the buyer had notice or knowledge that the milk was skimmed milk. The addition of annotto, whether injurious to health or not, is punishable under the statute.

The inspection and regulation of the sale of vinegar and oleomargarine is under the same department. In the case of the latter, the law provides that whoever sells oleomargarine or any other imitation of butter, shall have a label in plain sight upon the package, and that all carts peddling such articles, and all shops in which they are sold, shall show a sign announcing the fact.

THE CHOLERA.

The East still continues to be the chief seat of the cholera. In Marseilles, Toulon and some of the smaller towns of the French Riviera a few new cases occur from day to day, but no alarm is felt as yet. In Spain there has been a small outbreak in the province of Corunna since the 25th of July, but no official proclamation has been made. On July 28th one case occurred at Altona, but with that exception no cases have been reported from last year's seat of the plague. Smyrna has been declared infected since July 25th, though the number of deaths has been small. In Buda-Pesth the precautions taken on the first appearance of the cholera July 12th, have been successful, and only a few sporadic cases have occurred. In the provinces of Turkey there has been no special increase in the number of cases reported. Russia has not fared so well. While the epidemic in Moscow has been confined chiefly to the poorer classes with an average of about fifteen new cases a day, it has steadily increased in the provinces, especially in Podolia and Toola, where there have been nearly five hundred deaths so far.

The condition at Mecca is as bad as ever and becoming worse. Since June 8th there have been over 6,000 deaths in that city alone. In Jedda the death-rate is equally high; and the combined mortality of Jedda, Mecca and Minah is already over 15,000. The daily death-rate is about 1,000, and the pilgrims still continue to arrive and depart. It is estimated that there are now 200,000 of the faithful gathered in the vicinity of Mecca. The quarantine station at El Tor, which accommodates 11,000 only, is quite inadequate for the 40,000 pilgrims on their way. As they arrive worn and exhausted by the journey, they are in no condition to stand out against the disease. The death-rate is already reported to be large, but no figures are given.

The only point of immediate danger to our own country at present is Naples. The cholera made its appearance there July 16th, with four fatal cases; and a week later was reported to be prevailing quite generally, though not recognized officially by the government. So far there have been about 400 cases and nearly 200 deaths. Telegraphic reports state that the daily number of cases is not increasing, and the number of deaths is less.

MEDICAL NOTES.

Another "Diploma Factory." — "The Preparatory Medical College of New York" has ceased to exist since the arrest of the entire faculty and treasurer, a Dr. W. M. Rew, who sold diplomas for twenty dollars apiece.

Yellow Fever. — Reports from Santos show that the yellow fever is still widely prevalent. The daily mortality is among the hundreds. Business is at a complete standstill, and the hospitals are totally inadequate to care for the sick, who die faster than the bodies can be buried.

A New Medical School. — A new medical school has been organized and chartered in Richmond, Virginia, to be known as The College of Physicians and Surgeons. Dr. Hunter Maguire is the President of the Board of Directors.

A New Columbarium. — The United States Cremation Company has just dedicated a new columbarium in connection with its crematory at Fresh Pond, Long Island. It is a two-story building of white marble and contains six hundred niches for cinerary urns.

A Case of Blue-Illness. — Pic recently showed the Society of Medical Sciences of Lyons, the heart of a patient who died of cyanosis at the age of forty-two years. The cavities were dilated, the walls hypertrophied, and the auricles communicated by an opening large enough to admit a wheat straw. During life the man had been subject to bronchitis, and to cyanosis upon slight causes. Bleeding during attacks of cyanosis had relieved the patient and prolonged his life.

Hypnotism in Russia. — Hypnotic suggestion as a therapeutic remedy has received official sanction in Russia. The government has announced that physicians may have the right to apply hypnotism in the care of the sick, on the sole condition that they report to the authorities each case of its application with the names of the physicians present at the time. All announcement of "private sittings" is forbidden.

NEW ENGLAND.

The Garbage Crematory in Lowell. — For some time past a crematory of garbage has been in operation in Lowell and there seems to be much difference of opinion about its merits and defects. At a meeting before the Board of Aldermen, a petition was discussed, claiming that the odors from the crematory were offensive, and evidence was brought to show that its presence was detrimental to the health and religion of the community. This latter accusation was founded upon the allegation that the odor in a neighboring church was so bad that it was impossible to gather a congregation in it. The petitioners swore to six different kinds of odor, and about as many diseases caused by them, but this evidence was somewhat weakened by the defence, which showed that one of the principal objectors had entered a similar complaint against a glue factory some years ago, which had finally been decided in court to be unobjectionable and which is still working. An agent of the Board of Health gave evidence on the part of the defence that he had gone to the top of the crematory and smelt the smoke as it issued from the chimney, not only without injury to his health and his religion, but even without any unpleasant sensation. The Board finds it impossible to identify all of the numerous odors described, but believes that none of them came out of the crematory with the smoke. The matter is still under consideration.

NEW YORK.

State Board of Health Reports. — At a meeting of the State Board of Health held July 27th, Dr. Florence O'Donohue, of Syracuse, was elected President of the Board in the place of the Hon. Thomas Newbold, resigned. The bulletin of the Board states that the death-rate for June was 17.50, while that for the six months ending June 30th was 21.30. Four thousand three hundred deaths are attributed to the epidemic of influenza which began in March and is now practically ended.

The Electrocution of Taylor. — The execution of the murderer Taylor at Auburn prison on July 27th was accomplished in a very unsatisfactory manner. Immediately after the first shock, which rendered the man unconscious but did not destroy life, the armature of the dynamo became burned out and the instrument was consequently useless. It therefore became necessary to make connection with the Auburn city electric-lighting plant, and there was a delay of an hour before the second, and successful, application of the current. Among the spectators on this occasion was Dr. Nettie E. Jenkins, who was the first woman to witness an execution by electricity. She will probably not be anxious to witness another very soon.

Miscellany.

THE STATE BOARD OF HEALTH EXHIBIT AT CHICAGO.

Among the interesting hygienic exhibits at Chicago, that of the Massachusetts State Board of Health is particularly valuable. Besides the diagrams and charts illustrative of the statistics of life and health and comparative mortality, of diseases and epidemics, and the general work of a well organized Board of Health, there are several features of the exhibit which are especially interesting. The models of the Lawrence Experiment Station and the apparatus there used for study and research in municipal hygiene; the maps and plans of the Metropolitan Sewerage System; and photographs of the sewerage fields already in practical operation, gives one a new sense of the extent and importance of proper, thorough control of public sanitation. The Department of Food and Drug Inspection, showing types of injurious or fraudulent adulterations found in this State, is well worth a visit, if only to see the dishonest ingenuity of man.

The display of the official reports and blanks which are used for the routine work of the Board, are full of suggestion for physicians from small towns where local sanitation is just beginning.

METATARSALGIA.

Bradford,[1] in his article on metatarsalgia, spoke of the desirability of further evidence upon the nature of this affection. Morton reports six new cases. It will be remembered that Morton [2] accounts for the severe and paroxysmal character of the pain by referring to the anatomical relations of the plantar nerves to the bony structure of the foot. Owing to the setting back of the fourth and especially the fifth metatarsal joints they have more lateral motion than the other three toes. The base of the first phalanx of the little toe is on a line with the joint of the fourth, and the head of the fifth metatarsal bone when subjected to lateral pressure is, therefore, jammed against the neck of the fourth metatarsal bone or rolls under it to a slight degree, thereby pinching the branches of the plantar nerve distributed to the joint.

It is this pressure of a tight boot which demands the instant relief so characteristic of the affection. The frequent occurrence of a slight degree of this neuralgia may be relieved by careful selection of the shoes worn by the patient. Firm low-heeled shoes which allow no slipping of the foot may be sufficient to give relief. The obstinate and severe cases, however, yield only to operative treatment. According to Morton this should consist always of excision of the metatarso-phalangeal articulation which is the seat of pain, or of amputation of the toe above the joint. This view of the cause and treatment of metatarsalgia is opposed by Hoadley [3] on the ground of clinical and anatomical experience. He points out that while the fourth and fifth metatarsal bones are shorter than the

[1] Boston Medical and Surgical Journal, July 16, 1891.
[2] Annals of Surgery, June, 1893.
[3] Chicago Medical Recorder, July, 1893.

others, the head of the fifth is not sufficiently far back to allow it to fall against the neck of the fourth, and although the outer bones are movable and can roll up and down it is not possible for them to slide above or underneath as described by Dr. Morton.

"Another reason for believing that this supposed cause for the neuralgia is not correct, is that the nerve which supplies the toe, and the one that has been accepted as the neuralgic nerve, could not possibly be implicated if one bone pressed upon the other, as described, as the nerve lies below the transverse ligament and not between the heads of the metatarsal bones. Without regard to the length of the metatarsal bones, it is quite possible for the nerve to become injured by lateral compression, as the foot will fold upon itself so as to involve the digital nerve. It being the digital nerve that is involved, the articulation, or the articular nerves, have but little to do with the painful affection."

Accordingly, the author advises the trial of thick leather or of metal insoles to prevent the rolling together of the foot. If the neuralgia is persistent, he recommends the division of the internal branch of the external plantar nerve, the one usually affected. His clinical experience bears him out in this belief as the report of six cases goes to show. The only case not relieved by proper shoes was at once cured by excision of the nerve on which was found a small neuroma. The advantage of being able to offer a patient a simpler operation than excision of a joint of the foot is worth consideration.

DIET IN GLYCOSURIA.

WHATEVER the underlying cause of glycosuria may prove to be, there are certainly two well-marked clinical forms of the disease. The simpler one, in which the glycosuria is dependent upon and commensurate with the ingestion of saccharine or starchy foods, responds well to a rigid diet, and by careful regimen may be entirely controlled. The graver form in which the sugar seems to be formed in the body from the albuminoids, is controlled with great difficulty even by the most rigid diet. Schmitz,[1] after careful study of several of these cases, found that the excretion of sugar, instead of being diminished by a strictly nitrogenous diet, was increased so soon as the meats and broths were in great excess over the carbohydrates.

Guided by this fact and the great distaste for nitrogenous foods which the patients all had, he changed the character of the diet. Meat, eggs and fish were given in small amounts only; and he ordered more varied foods, containing fats, but scanty albuminoids and starches. Under this change the patient's strength, appetite and weight increased, and the sugar excreted diminished in some cases four per cent.

The diagnosis between the two forms is made particularly upon the time of sugar excretion. In the simpler form the urine contains sugar chiefly by day and shortly after eating; the urine which is passed early in the morning before breakfast containing little or no sugar. In the grave form, the sugar being formed more independently of the diet, the urine shows less difference between night and morning; and it may usually be considered when the urine contains sugar eight hours after the taking of food, that the case is of the graver form and that the sugar is formed from the albumens.

[1] Deutsche Med. Woch., 1893, No. 27.

In this latter class he gives the following diet:

For Breakfast: Preferably, cocoa, when pure and unadulterated, on account of its fat; a little milk; and either twenty to thirty grammes of rye, or forty to fifty of white bread. If the cocoa is not liked, the patient may have tea or coffee, and an egg-cake made as follows: two or three teaspoonfuls of oatmeal, one egg, and two teaspoonfuls of sour cream are beaten together, salted, and baked with a little fat or bacon.

For Lunch: a glass of wine, and a sandwich of twenty to forty grammes of bread and some sardines.

For the Noon Meal: a broth with a little rice or vermicelli (two pounds of meat should furnish enough broth for three meals); a little fish; potatoes, if not mealy; vegetables very sparingly — as young beans, spinach or cabbage — may be given. Potato salad is often much relished, as are cakes made of raw grated potato-meal, as above described.

For Tea: a meal as at noon, but always varied. Dry wine may be allowed.

He reports three cases so treated with a scanty nitrogenous diet, in which the sugar diminished very much, although the daily ingestion of bread was nearly one hundred grammes. Under this regimen also the acetons disappeared from the urine.

Saundby[2] offers the following receipts for diabetic food, which he has found palatable and not expensive.

Almond cakes: One pound of ground almonds; four eggs; two tablespoonfuls of milk; a pinch of salt. Beat up the eggs and milk, and stir in the almond flour. Bake in flat tins in a moderate oven for forty-five minutes.

Cocoanut cakes: Three-fourths of a pound of fine dessicated cocoanut: one-fourth of a pound of ground almonds; six eggs; half a cup of milk. Mix as in the other cake, and bake for twenty-five minutes.

Both these cakes keep well for a week.

Blanc-mange made of Iceland moss, and sweetened with saccharine, is absolutely free from injurious constituents, and very palatable.

THE NON-OPERATIVE TREATMENT OF SALPINGO-OVARITIS.

THE importance and proper relations of the non-operative treatment of salpingo-ovaritis are well shown in a recent paper by Dr. Shoemaker, of Philadelphia.[1]

Certain cases of pelvic disease are, of course, unmistakably surgical. A large number of women, however, have of late years been treated most lavishly by surgical procedures, have desired or allowed their uterine appendages removed for chronic tubal inflammation, when with proper and patient treatment the operation could have been avoided.

The questions chiefly to be considered in any given case are:

(1) Will the woman be improved by the operation, and ought it to be done in her case?

(2) What are the prospects, temporary and permanent, of systematic non-operative treatment?

The first question will be answered differently for each case. The social, personal and physical conditions of the patient are all factors to be considered. The long and tedious road of douching and massage cannot be opened for the working woman, whose right to an early operation is far greater than that of a

[1] Annals of Gynecology and Pædiatrics, vol. vi, No. 10.
[2] Birmingham Medical Review, May, 1893.

woman of riches and full leisure. The domestic undercurrents are by no means to be ignored. There are a small number of cases in which the adhesions are old, firm and numerous, and the cause of obstinate reflex disturbances. These should be operated upon early, where they occur in women dependent upon their own labor for existence. At first examination, however, it is not easy to distinguish old adhesions from firm, new ones, which may, however, be absorbed.

The second question can be answered more categorically. In the author's experience no case of chronic pelvic inflammation can be cured permanently by non-operative treatment. There will always be the line of weakened resistance and the focus for a lighting up of the old trouble. It leads to far better judgment and treatment of a case to have this point well understood; it is always a question of relative palliation.

Under systematic treatment, faithfully carried out, both by patient and physician, the patient's health can be so restored, the attacks of inflammation so lessened and alleviated, that her life may become of comfort and usefulness. The rest-cure, massage, careful tamponing and douching must be unremitting. Tampons of elastic wool were found more satisfactory if covered with a thin layer of cotton. Where much tenderness is found, a useful addition to the well-known borogly ceride tampon is ichthyol, which when made into an ointment with four parts of lanolin, may be put on the tampon against a tender region. This substance seems to have a decided influence over subacute inflammation, and serves to lessen tenderness very rapidly.

A true conservative treatment, which is not an easy dalliance has much promise, and should receive greater attention than it has had heretofore.

VISCERAL PHLEBOTOMY.

Harley[1] claims great success in the treatment of hepatic inflammation by withdrawing blood directly from the congested liver. His method consists in piercing the viscus with a long trocar about seven millimetres in diameter, so as to "wound one or more blood-vessels of sufficient caliber to yield a free stream of blood." After sufficient blood is withdrawn the finger is held over the mouth of the trocar till the stream of blood has clotted back into the viscus. The trocar is then withdrawn and the wound closed by adhesive plaster and a bandage applied.

He reports successful treatment by this means of several cases of chronic and acute hepatitis, and has seen it applied to pulmonary congestion. He seems to have met with no cases of subsequent internal hæmorrhage, a danger not to be disregarded, for his only reference to this occurrence is indirect. He says, that on withdrawing the instrument it is important to get the clot in the canula to break off from that in the canal so as to leave the latter behind, in order that by its presence there it may prevent any oozing of blood from the organ. This is best done by giving a slight twist to the canula at the moment it is felt to leave the organ. The external puncture is closed by adhesive plaster and a flannel bandage bound firmly over it to bring the internal surface of the parietes against the wounded organ, to prevent the possibility of accidental internal hæmorrhage.

[1] Journal of the American Medical Association, vol. xxi, No. 4.

It is hardly probable that the recommendation to extend this procedure to all the viscera, as the spleen and kidneys, will meet with a wide acceptance.

THERAPEUTIC NOTES.

The Care of Catheters. — Gouley[1] gives the following directions for the care of catheters. Web catheters should be kept at full length to prevent cracking. In cold weather they should be warmed slightly before being shaped for use. In spite of good care web catheters are liable to harden in a few years, especially if not in constant use: they then lose their shape, even if they do not crack, and should be discarded. After use they should be carefully dried inside as well as out, and kept wrapped in *dry* antiseptic gauze in metal cases. Soft-rubber catheters should be kept at full length in *moist* antiseptic gauze, away from the air, as exposure to it causes the rubber to become dry and brittle. The life of a soft-rubber catheter is short at best, but when in daily use and annointed with fatty lubricants, they swell and become soft and useless in a few weeks. Where continued daily catheterization is necessary, it is best for the patient to have a set of ten or twelve catheters and to use two each day, so that the same catheter may be carefully dried and sterilized and used only every fifth or sixth day. Both web and rubber catheters are much injured by fatty substances, and even by vaseline, though to a less degree. The lubricant should be unirritating to the urethra and contain no fat or free alkali to deteriorate the varnish of web catheters or to soften the rubber catheters. The following formula has been found satisfactory: Three hundred and sixty grains of white castile soap, powdered, are added to two fluid ounces of boiling water and stirred until a homogeneous jelly is formed. Enough hot water is then added to bring the whole up to 1,200 grains, after which the mixture is strained through cotton gauze and one-half a fluid-ounce of tincture of quillaja poured into it. This mixture when cool has the consistency of honey. A little carbolic acid may be added and the lubricant kept in collapsible tubes.

Piperazin in Uric Acid Diathesis. — Witzack reports the following conclusions from the use of piperazin in cases of uric acid diathesis:

(1) In all cases the diuresis was noticeably increased; the daily amount in one case of uric acid arthritis being more than doubled.

(2) The specific gravity of the urine was always lowered; the urine was acid, but never neutral or alkaline.

(3) The appetite was not affected, nor was there any general disturbance from the drug.

(4) Subcutaneous injection even of the smallest doses was always painful and accompanied by considerable infiltration around the point of injection. Abscess formation was avoided with great difficulty.

(5) The salts of the drug were more reliable than the drug itself since they are less hygroscopic and allow a more accurate dosage.

(6) The drug should be given in sufficiently large doses, one gramme a day, over a considerable period before the effect can be rightly estimated as some patients respond slowly.

Deaths reported 4,675: under five years of age 2,756; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 1,823, diarrhœal diseases 1,534, consumption 341, acute lung diseases 229, diphtheria and croup 104, typhoid fever 50, whooping-cough 33, cerebro-spinal meningitis 32, measles 25, scarlet fever 25, malarial fever 10, erysipelas 3, small-pox 2.

From whooping-cough New York 9, Philadelphia 7, Chicago 5, Pittsburgh 4, Washington 3, Brooklyn, Cincinnati, Cleveland, Milwaukee and Brookline 1 each. From cerebro-spinal meningitis New York and Chicago 8 each, Brooklyn and Cleveland 5 each, Philadelphia 2, Boston, Washington, Worcester and Brockton 1 each. From measles New York 7, Chicago 5, Philadelphia and Pittsburgh 4 each, Brooklyn 3, Lynn 2. From scarlet fever New York 6, Chicago 4, Philadelphia, Brooklyn, Boston, Milwaukee, Cambridge and Springfield 2 each, Worcester and Everett 1 each. From malarial fever Charleston 4, Brooklyn 3, Nashville 2, Cleveland 1. From small-pox Philadelphia 2.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 22, 1893, TO JULY 28, 1893.

Leave of absence for one month, to take effect when his services can be spared at Fort Wingate, New Mexico, is granted MAJOR LOUIS M. MAUS, surgeon, U. S. A.

Leave of absence for two months, to take effect on, or about, September 15, 1893, with permission to apply for an extension of one month, is granted FIRST-LIEUT. BENJAMIN L. TEN EYCK, assistant surgeon, U. S. A.

CAPTAIN WILLIAM B. DAVIS, assistant surgeon, is relieved from duty at Fort Sam Houston, Texas, and ordered to Fort Brown, Texas, for duty, relieving CAPTAIN GEORGE H. TORNEY, assistant surgeon.

CAPTAIN TORNEY, upon being relieved by CAPTAIN DAVIS, will proceed to and take station at Philadelphia, Pa., as attending surgeon and examiner of recruits at that place.

CAPTAIN LEONARD WOOD, assistant surgeon, is relieved from duty at Presidio of San Francisco, Cal., and ordered to Fort McPherson, Georgia, for duty.

CAPTAIN LOUIS W. CRAMPTON, assistant surgeon, is relieved from duty at Fort Spokane, Washington, and from temporary duty at Hdqrs., Dept. of Colorado, and ordered to Baltimore, Md., as attending surgeon and examiner of recruits, relieving CAPTAIN CHARLES B. EWING, assistant surgeon.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 29, 1893.

H. J. BABIN, surgeon, to temporary duty at Naval Station, Fort Royal, S. C.

A. R. ALFRED, assistant surgeon, from the "Franklin" and to the "Minnesota."

J. M. MOORE, assistant surgeon, from Norfolk Hospital and to the "Franklin."

E. KERSHNER, medical inspector, to duty on board the U. S. S. "New York."

J. F. URIE, passed assistant surgeon, to duty on board U. S. S. "New York."

H. D. WILSON, assistant surgeon, from the "Minnesota" and to the "New York."

B. H. KIDDER, medical inspector; H. M. WELLS, medical director; FRANK ANDERSON, surgeon; CLEMENT BIDDLE, passed assistant surgeon, granted leave of absence.

RECENT DEATHS.

JUSTUS CARRIERE, M.D., has died in Strassburg, aged thirty-nine years. He was a grandson of Von Liebig and Professor of Zoölogy at Strassburg.

JOHN RAE, M.D., died in London, Eng., July 24th. He was a noted Arctic explorer and had charge of one of the expeditions of Sir John Franklin.

BOOKS AND PAMPHLETS RECEIVED.

Eczema Infantile. By B. Merrill Ricketts, M.D., of Cincinnati, O. Reprint. 1892.

College of Physicians and Surgeons, Richmond, Va., Announcement, Session of 1893-94.

Report of the Commissioner of Education for the Year 1889-90. Two volumes. Washington. 1893.

Laws Relating to Public Health Passed by the Ninth General Assembly of the State of Colorado. 1893.

Apparent and Actual Mortality. By F. D. Bullard, A.M., M.D., Los Angeles, Cal. Reprint. 1893.

Proceedings of the Association of Medical Officers of American Institutions for Idiotic and Feeble-Minded Persons, Session, 1892.

Bacterial Poisons. By N. Gamaleïa, M.D., translated by E. P. Hurd, M.D. Physicians' Leisure Library. Detroit: George S. Davis. 1893.

Weekly Abstract of Sanitary Reports issued by the Supervising Surgeon-General, Marine-Hospital Service. Vol. VII. 1892. Washington. 1893.

The Indications for Amputation in Chronic Disease of the Larger Bones and Joints, with a Report of Seventeen Recent Cases, Including Three Successful Amputations at the Hip-joint. By J. E. Summers, Jr., M.D., Omaha, Neb. Reprint. 1893.

Lectures.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XII.

SPECIAL FRACTURES.

Fracture of the Greater Trochanter. — It happens occasionally that a person breaks off the greater trochanter. That can be easily diagnosticated, because the trochanter is so superficial that we can feel it through the tissues, grasp it and detect crepitation.

If it is a fracture of the trochanter alone, then we can apply treatment by the pelvic belt and gentle extension, and keep the parts quiet, and we are sure of union. If it is a fracture through the trochanter and the neck, we must treat it as a fracture high up, either in the straight position, or sometimes, if the fracture occurs below the trochanter minor, then in the double-inclined-plane position, which will favor the approximation of the fragments.

When the femur happens to be broken off just below the lesser trochanter, the upper fragment is strongly pulled upon by the psoas and iliacus muscles. The injury throws them into spasmodic contraction. They are ordinarily so strong as to move and evert the fragment. Everything is gone except this little piece, and they seize this and turn it, and tip it outwards. The shaft goes, usually, backwards; and no approximation of the fragments is possible, without great care. It is sometimes possible in the straight position to get this fragment down to match the shaft. If you are unable to do this, you must bring the lower fragment up. So that it is this class of fractures that is best treated on the double inclined plane. That is Nathan Smith's method of treating fractures of the thigh. Nowadays most fractures of the thigh are treated in the straight position. It is a noteworthy fact that Hippocrates treated fractures of the thigh in the straight position. People got dissatisfied with that; and two or three centuries ago they treated them all on the double inclined plane. Now they are almost all treated in the strictly horizontal position, once more.

When an old person falls and breaks the neck of the thigh bone completely off, you apply treatment; and the two questions always asked are: Is the patient going to be lame afterwards? You can safely say, "Yes." If they do well they will go on crutches a long while. If they do extremely well, they will be able to use a cane; but not be able to go without a cane, in all probability, for the rest of their lives. How long are they going to be confined? That you must put at a long period. The treatment that you apply to complete fracture of the neck would not cover more than six, or eight weeks; but the subsequent recovery of the powers of the old person always consumes months; and four to six months is perhaps none too long to say, before they get to moving about freely; and, of course, in a limited class of cases you would say, this person is so old and feeble, having already reached the age of eighty, or more perhaps, that it is hardly worth while to subject him to hard confinement and to apparatus; but the better way is to put the patient of that age upon a soft bed with springs and mattress so arranged and divided, that the bed can be tilted about on a double inclined plane; and subsequently get him on a lounge or chair of the same plane; and look after the bladder. Look after bed-sores. Keep up the nutrition without applying rigid apparatus. Be cautious about applying bandages firmly to the parts, for you run a great risk of so interfering with the circulation, that gangrene may be set up in the toes, to which they are extremely liable. In the first place, as you know, the venous circulation on the surface is extremely sluggish; the vessels are much dilated. In addition to that there may be atheroma of the arteries, which has reduced their calibre and elasticity so that the nutrition of the extreme parts of the foot is very poor. Such a limb will stand very little exposure to cold; will heal very slowly if it is injured; will slough very readily if it is compressed by a bandage or apparatus.

Fracture of the Femur. — It is this bone which gives rise to the greatest number of cases of shortening; conspicuously so because it supports the whole weight of the body, and because it is small; and also, especially, because the muscles that are attached around it are so powerful. When the femur breaks, shortening is immediate and considerable, and amounts frequently to an inch within the first few minutes. The deformity of the limb is very marked. The limb appears twisted out of place as well as helpless. The muscles above are irregular, and the deformity of outline is always considerable in fracture of the femur. Shortening and deformity. In addition to that if you draw the part down, you get crepitus; and a hinge or false joint in the middle of the thigh, for instance, is very conspicuous when you try to lift so large a portion of the body, so that the signs of broken femur are marked from the beginning.

In consequence of the power of these muscles shortening is very difficult to overcome by extension, and it frequently happens as the result of treatment that a considerable shortening remains. I think I said in the beginning of this course that recent measurements conducted in a number of museums of specimens of fracture of the femur, for instance, had proved that that bone especially, of the long bones, never united without shortening. This may be qualified a little perhaps in the case of the femur of children, where the break is usually transverse, and where union without shortening frequently occurs. In the adult shortening is the rule.

How much shortening is to be considered a fair result? Experience has proved that a patient will walk without perceptible limp with three-fourths of an inch shortening. He may need possibly another lift upon the sole and heel of the boot, but will not limp perceptibly with three-fourths of an inch shortening; for the pelvis tilts, and the whole side of the body accommodates itself to that shortening, without showing appreciable lameness. What is called a first-rate result in broken femur is one-fourth of an inch shortening. One-half inch does not make us ashamed. Three-fourths of an inch is not desirable; but still we may feel that the patient is not going to be lame, and conspicuous to himself and others. Beyond three-fourths of an inch marked lameness occurs; and instances are seen, frequently, in which either without treatment, or from unfortunate treatment, shortening results of from one to one and a half inches.

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

We may then in attending a fracture of this bone expect to be able to make an easy diagnosis; expect to have a case that will require treatment and a great deal of care to avoid shortening; and expect to have some shortening any way; and it is just as well, if anything is said upon the subject, for the patient and his friends to understand from the beginning, that no treatment can make a broken bone, of that character, as long as it was before. They must be made to understand that it shortens in mending. That is true; but there is another point true, for which we are responsible if we allow it to occur; and that is this, that after union has taken place to a pretty firm degree, if we allow the patient to go about too soon upon such a bone (as it bears such a weight and is so small), subsequent shortening will take place after union has occurred, from pushing up, shortening and shrinking of the soft callous union, which has not yet become bone. These are the cases that get out of bed at the end of six weeks; come out with a shortening of one-fourth of an inch, and are found to have increased the shortening by another one-fourth or one-half of an inch. It is remediable. The limb can be drawn down and the original length secured; but, unfortunately, unless we are on our guard, it is liable to occur, and very frequently it is not detected. Some shortening we are responsible for; and that is this kind; but the shortening that occurs in the beginning from the mending of the bone we are not responsible for, at all; and if the patient escapes with not over three-fourths of an inch shortening, he is not going to be essentially lame.

In all the ordinary fractures of the femur, anywhere from an inch or two above the popliteal space to an inch or two below the trochanters, the treatment is the same. In old times it was treatment in the straight position. Two or three centuries ago treatment vibrated back to the double inclined plane. Latterly, it has returned to the straight position; and it is the rule now that all fractures of this kind that I spoke of are treated in the horizontal position, and by extension and counter-extension. Since the use of the weight and pulley, which, by the way, is mentioned far back in the Middle Ages; and since the use of plaster extension, which was used in 1771; since the re-discovery and re-use, so to speak, of these two methods of treatment, the treatment of fracture of the femur has become very much simplified. When I was a student, it was customary to treat in the straight position; but the counter-extension was made by a perineal strap, and the extension by having a long splint pocketed in the belt; a foot-piece attached, movable by a screw; the foot being fastened to the foot-piece, and the screw being turned, the leg was extended. Then you pulled against the perineum entirely, to the great suffering and annoyance of the patient. Sores occurred. Many of the hospital apparatuses in those days had a padlock to prevent the patient from unbuckling his straps. The result was sloughing heels, sloughing perinei, and general discomfort. This did not occur in all cases; but it was liable to occur in a good many cases. Now, by the use of counter-extension, by raising the foot of the bed, and by the plaster-extension, we have overcome, practically, all these miseries, and have as good results as they had before. One surgeon, I think, has undertaken to treat fractures without extension, by the immediate application of plaster-of-Paris, but the results have not been very successful. You will find in "Hamilton's Surgery" a table of results of treatment by plaster, which is not very encouraging. The trouble is this: The limb is drawn down into place, the plaster-of-Paris applied, and at first all goes on well; but within a few days, when swelling has subsided and the leg begins to shrink, it absorbs more and more as time goes on. It soon lies like a loose substance within a case; and shortening of the fragments takes place inside the plaster, out of sight; and it may result in a union with considerable shortening.

Extension and counter-extension, on the whole, are the best methods. It is not a part of this course to show the application of apparatus. I only undertake to lay down the rules. Inasmuch as the fracture of the thigh-bone is one of the most serious we have to treat, it seems proper that these rules should be laid down very slowly and exactly with regard to the apparatus; and that I hope to do plainly now.

Counter-extension, in the first place, by raising the foot of the bed at least four inches. This is useless if you allow the patient a bolster and two or three pillows, because you immediately tip up his body and shoulders on a double inclined plane, and do not get the weight of the thorax and head pulling. The head should literally be lower than the heels, for the first few days until the muscles have got tired out, to make this treatment perfectly successful. Moreover, the bed must be very firm and hard. A bed made of wire or of soft springs is not suitable, unless there are put under it three or four cross-pieces of wood to prevent sagging of the apparatus; for the upper fragment may be tilted up by the sinking of the apparatus. Everything must be square, straight, horizontal and smooth, and the foot of the bed raised four inches; and if any pillow at all is allowed, an extremely thin one, and one only. The patient must necessarily be forced and instructed to lie on his back, which he is very reluctant to do. He suffers a good deal; has backache and wants to turn; and if he turns he disturbs the fragments. Extension is made by long strips of plaster, water-proof plaster, spread on heavy cloth, which will not soften up under the influence of perspiration or accidental wetting — two long strips, which are carried up to the end of the lower fragment, always above the knee-joint, and then surrounded with circular, or spiral strips enough to keep them in place. Fasten this around a cross-stretcher, to a cord, which runs over a pulley, and to which is attached a weight. It is of no consequence what the weight is made of, as long as it is a weight of a certain definite amount. A strong man, in the early stages, requires twelve or fifteen pounds' weight to pull down the femoral muscles. Ten to fifteen pounds is a common weight, and five to six for a child. Five to ten for a child or young adult; ten to sixteen for a fully developed and strong person. We must be guided a little by the size of the thigh of the individual, by the power of the muscles, by his weight. Weight is to be put on until the thigh is brought down to a length equal to the other, as determined by careful and repeated measurements. We may not accomplish this the first thing, but ought to accomplish it in twenty-four to seventy-two hours. It is found that, after a few days, the muscles get so tired that they will give out considerably, and the length of the limb can be maintained with a diminished weight. It is questionable, I think, whether it is desirable to have sixteen pounds pulling for six weeks upon a leg. It is conceivable that we may separate the fragments,

may delay union in that way. We should allow them some chance to come together, but at first great power has got to be used. When the muscles get tired, we take off several pounds, and go down from sixteen to twelve, or from twelve to nine or ten, according to the amount which was first used.

You must also be extremely careful that friction about the bedstead, friction of the foot pressing against some rod or cross-piece, friction of the heel pressing against the edge of the mattress does not defeat your object in getting perfect extension. It is important that the heel should swing free from the bed, and be separated by a pad in the hollow of the ankle, so that the heel may lie off and not touch. The heel is the part above all others that does not bear pressure well. In health it is almost wanting in sensitiveness, as you know; but pressed upon, it becomes as tender and aching as a diseased bone; and when it once sloughs, it of course being of a thick and semifibrous and feeble tissue, it repairs very slowly; makes a disastrous ulcer; which is a long while in skinning over, so that the patient can move about; so that ulcerations over the end of the os calcis are to be dreaded. You can see in the skeleton how much of a protuberance this bone makes, and the importance of having this lifted up by a pad.

The next point is to prevent the lower fragment and the knee from rolling out, which they will do if not supported; to avoid eversion; to keep the great toe on an exact line with the inner border of the patella; and in order to do that we have got to immobilize the places where motion can occur.

What are these? The hip-joint, knee-joint, to a less degree the ankle-joint. These three joints must be immobilized; and the foot inverted; the toe kept straight up, and on a line with the inner border of the patella. We accomplish this best by the long outside splint. This is a relic of the old period. It must extend down below the foot, and must be placed on the outside of the limb and fastened so that the limb shall be inverted a little and not allowed to turn out. It is a part of the old apparatus, but does not fulfil the same office as in the old apparatus. In the old apparatus it was the means of carrying on the extension. In the new apparatus it is simply to prevent rotation; and I wish to insist very strongly upon that point; for many people make the mistake of thinking that this is a long board which lies down beside the limb in the bed as a splint, which is keeping up the extension, and keeping up the length of the limb. It has nothing to do with it. It prevents rotation, and prevents motion of the joints, that is all. In order that it may keep a perfectly vertical position it is useful to have a cross-piece attached to it, so that we have a long piece coming down, and a piece crossing below, but not touching the foot, to hold the splint upright on its edge. We have to have a belt and pocket to confine it around the body, like a swathe. It can be carried up to the arm-pit, and fastened around the body.

So far, then, we have drawn the leg down, and held it by weight; have prevented rotation, and motion of these three joints. It is also necessary to compress the muscles immediately around the fragments of the broken bone; and this is done by means of four narrow pieces of wood, like shingles, placed above and below and on either side of the thigh, to compress the muscles which are about the fracture. No bandage should be put on the thigh under the splints. That cannot be too strongly insisted upon. The splints should be properly padded. They should be fastened on with three or four inch wide webbing straps and buckles. In that way you can watch the circulation of the part; see the amount of swelling; tighten or loosen at any time; and the object of these splints is only to keep the parts still. When this is done, that is all. You have got the length by pulley from the foot; counter-extension by the weight of the body; you have got position; compressed the muscles, and held the parts in position; and after two or three days you may begin to take off weight.

How long should this be kept on? About six weeks in an adult. Much less than that, for a broken femur, in a child. At the end of six weeks, take off the entire apparatus; strip the patient completely; let down the foot; measure to see the length; and gently lifting the ankle and foot, and putting the hand upon the trochanter, rotate to see whether you have union. If you have union, and fair length of the limb, it is very satisfactory; but this union is of the softest possible character; will not bear the weight of the limb; and certainly no moving about. Now extension by the weight and pulley may, perhaps, be given up, as long as the patient remains in bed; but in place of that put on a plaster-of-Paris, or dextrine, or starch, or some firm bandage, which extends from the toes to the groin, and compresses the parts evenly, and holds the united femur in its proper position. After that the patient should lie in bed two weeks longer; then sitting up may be allowed; moving around with crutches without putting the weight of the foot on the ground. Still keep on a light plaster or dextrine bandage for three or four weeks more; and if it shrinks and the leg wastes, as it usually does, it can be cut open, and fastened with external straps so as to make a snug evenly-moulded case for the limb. At the end of three months, it is safe to let the patient put weight upon the limb; but it is six months before he can lift on it and shovel, as with the other leg.

In the upper third of the femur a modification of this treatment is required, on account of the fact that the psoas and iliacus muscles attached to the inner trochanter seize upon the upper fragment and tip it up and out. In order to make the lower fragment match it, we must put the leg in the Nathan Smith splint.

When we come to the breaks of the lower part of the femur we meet a new difficulty. The two heads of the gastrocnemius muscle are strongly inserted into the posterior part of the femur. The moment the shaft is broken off, they pull on the two condyles and draw the lower fragment directly back into the popliteal space; and occasionally make a laceration of the vein, or an abscess, if not properly treated. Now this requires extension in the same position, but, in addition, a padded ham-splint to go in the popliteal space, to force up this fragment, while extension is kept up in the ordinary way. The result of treating the fracture in this way is generally good.

In all these fractures of the femur we are obliged to keep the knee-joint so long stiff and motionless, in the course of the treatment, that fibrous anchylosis is always the result; and the patient, at the end of three months, goes about with a stiff knee, which he is some time in overcoming. This will, with a little care, cure itself; does not need violent pumping, or friction, or massage. It is very prone to inflammation. I

have seen, after fractures, when the limb had got strong and the patient was going about, have seen him put back by injudicious movements of the joint, which brought on synovial accumulation. The patient will overcome the stiffness himself, by natural means. Encourage him to sit on the edge of a chair, and lower his foot-stool an inch a day.

Fracture of the Patella. — The knee-pan almost always breaks transversely, and frequently the lower fragment breaks into two pieces. Unfortunately the fragments are very seldom exactly alike in size, and these peculiarities explain why it is so difficult to get good union between the fragments. If we had a perfectly square break across the middle of the patella we should be able to hold the fragments more firmly and evenly and get better union, but we almost always have to deal with one large fragment and one small fragment, and frequently with one large fragment and two small irregular fragments. You will see at once how much these increase the difficulty of coaptating the parts or of making them unite. This being a sesamoid bone, developed in the tendon, has no great active or reparative power, and is incapable of uniting by bone, unless provoked by some foreign substance. A simple fracture, by wiring, will unite by bone; but if left to the processes of nature it will not unite by bone. The lower fragment is fixed, tied to the tubercle of the tibia by the ligamentum patellæ. The upper fragment is movable, fastened to the quadriceps femoris, and pulled up violently by the contraction of the rectus muscle. This separation usually takes place at once; and when we see a patient with a broken knee-pan, we generally find that considerable separation already exists. If untreated, and the patient is allowed to go about, this increases more and more, until, in one extreme case I saw at the hospital, of a sailor, there were between four and five inches between the two pieces of the patella. You may remember that the vasti muscles are inserted into the sides of the tibia and fibula by very strong extensor tendons, which are flat and fascia-like and firm. They form a sling which lifts the leg, after the attachment of the rectus to the patella is broken off; and they are the salvation of the patient who has broken the patella. This sling becomes very much increased in strength; grasps the knee as the two hands would; and in that way the foot is held with considerable safety, and moves with considerable force.

Fortunately it happens after fracture of the patella that, although union is not by bone, yet a simple separation of the fragments with membranous union, is just about as useful as union by bone. Hamilton lays down the law that separation up to an inch gives as good a limb as close apposition of the fragments, with regard to future utility. In this case the patient is not only dependent upon the membranous union of his broken knee-pan, but also upon the sling of the two vasti extensors, which become enormously thickened.

On the other hand, we have the means, if we succeed in the operation, of provoking bony union by cutting down on the fracture, converting the simple into a compound fracture, washing out antiseptically, drilling the bones, wiring, forcing the wire to hold them in contact a good many weeks, finally untwisting and removing the wire, and then eventually healing up the part, if fortunate, without sepsis, or destructive suppuration in the joint. Whether the good to be gained by this procedure is worth the risk it entails, must be left with every patient and surgeon to judge for themselves. I think an important point to be borne in mind is this, that we should never lose sight of the constitution, age and vitality of the patient when we are considering the propriety of subjecting them to any operation of this kind. We have got, on the one hand, the certainty of ligamentous union with fair result to the patient, if he is well taken care of; on the other hand, a better and firmer union, if the patient undergoes a certain risk. Will he keep up nutrition; is he likely to go into the condition of delirium tremens; or to sink in any other way? On the other hand, if we think it more prudent to use the old method, he is pretty sure of getting a fair leg, any way.

The principles of treatment are to treat the leg in the extended position. The patient must not only lie flat upon the bed, but the leg and foot must be raised up from the bed at a slight incline, in order to relax thoroughly the rectus muscle. The rectus has two heads. One is fastened to the pelvis just above the anterior inferior spine. We cannot relax that head unless we bend the femur on the trunk, and that is the object of lifting the foot a little higher than the bed. The fragments may be drawn together by a plaster, or figure-of-8 bandage; and finally a plaster-of-Paris bandage may be applied to the whole limb; an opening being left through which we can watch the fragments. This treatment cannot be applied at once. The fracture is a break into the knee-joint; and the injury, in consequence, is pouring out blood, and there is leaking into the joint. There is also a large effusion from the synovial sac, and we have a state of acute synovitis and ecchymosis; therefore we cannot apply this treatment, at first. You find, at first, the leg cool and the fragments separated, and you say "we can treat this at once," but the next day, you find the synovial sac full of fluid; the fragments wholly separated; the parts extremely tender; the surface black and blue, and risk of destructive suppuration in the joint, if you persist in harsh treatment.

The early treatment of fracture of the patella must be, in almost any case, to put the limb on a ham-splint; place it on pillows on a soft bed; to treat the synovitis for the first few days, sometimes by evaporating lotions, sometimes by cold, sometimes by leeches; and, after this, by more stringent treatment. I suppose this treatment would not apply to the case where you were to cut down and wire it.

The trouble about these fragments is not so much that we cannot draw them together, as that they tilt. Any pressure on the edges tilts up the middle; and the broken surfaces, instead of lying in contact perfectly, rise up, and it is difficult to control them. Malgaigne's hooks are, no doubt, an excellent means of holding the fragments perfectly in apposition. The plaster; the figure-of-8 bandage; the method known as Sauborn's, which consists in putting two rollers above and below the patella and applying plaster up and down the limb, and twisting it with a stick over the rollers, are also sometimes very good methods of keeping the fragments together. I think we should be reasonably satisfied if we can hold them together so nearly that no more than a quill or pencil can be laid between the fragments while treatment is going on; and if the limb is immobilized, you will get good union. That union is liable to stretch, at any time, for four or five months. Hamilton says, after five months, union is strong enough

to resist anything. Consequently, in the first place, the primary treatment must be very long, three months, at least; and subsequently to that, the patient must wear a ham-splint, with a joint, for two or three months more. I mean a ham-splint so made that, although it has a hinge in the back, it can only bend to a slight degree, and brings up by a catch, so that the patient cannot possibly drop.

What is the consequence if he gets an accidental early bending or fall? Re-separation of the fragments. This happens very often indeed. The patient is going about the wards and begins to feel pretty strong; his crutch slips, and that leg gives out at once; and the fragments are more widely separated than ever. Unfortunately, re-union is much slower and poorer and more imperfect than in the first place; and it is a great disaster to happen, in addition to the loss of time, because he never gets so good a leg as before.

Patient treatment for months. Care afterwards for many months later. Wearing this ham-splint for more than five or six months, perhaps; and finally, the patient will get a very useful limb. It is an annoying accident. For the size of the bone and of the injury, it entails more delay and loss of utility of the limb, than the fractures of a great many larger bones.

Fracture of the Tibia. — The tibia never breaks alone, I think, except in consequence of a direct blow. When it is broken alone, the fibula is a splint for it and holds it in place.

The treatment is very simple. A plaster can be put on; and the fibula will hold it in place. There cannot be shortening; and union will take place in four weeks.

Fracture of the Fibula. — When the fibula is broken alone, it gives way about two inches above the ankle-joint, as a rule, where the bone becomes quite thin. It always occurs by the same sort of violence that gives what we call a sprained ankle. When a person has a sprained ankle he steps off of some height and turns the toes in, or the foot into the position of varus. The ordinary sprained ankle consists in tearing some of the ligamentous fibres, and loosening the joint. The same sort of accident, in some patients causes fracture of the fibula. Unfortunately fracture of the fibula one and a half or two inches above the joint is often mistaken for a sprained ankle; and so treated, with disastrous results. The sprained ankle gets better at the end of ten days; but at the end of ten days the broken fibula is just as bad and painful as ever. Some one then makes a more careful examination, and detects the fracture. It is detected by placing the two thumbs on the fibula, and springing the bone up and down, and comparing it with the other leg. In the limb where the fibula is broken you have perhaps crepitus and localized pain and tenderness; a little irregularity of the surface of the bone; and it springs up and down, under the thumb, like two pieces of whalebone. People can walk with this fracture. Booth shot Mr. Lincoln and went off with this fracture, and rode two nights; and if he had not had to go through other hardships, probably he would have done very well. People can go about with that fracture, but it will not get well.

Dupuytren's splint is a good one. Apply on the inside of the limb and bandage over. Simple plaster-of-Paris, put on, is sufficient; and with the plaster on, the patient can get on crutches, and move about very soon without putting weight on the limb.

The essential point in regard to this injury consists in its diagnosis. Its treatment is easy, and its cure certain.

Fracture of the Tibia and Fibula. — Fracture of both bones of the leg almost never takes place on the same level. One is above or below the other. As a rule, the tibia is low down and the fibula higher up. Moreover, fractures of the tibia anywhere between its upper and lower thirds are almost always oblique from before backwards and upwards, so that the upper fragment has a sharp shell of bone which lifts up against the skin. If the fibula is also broken, the gastrocnemius muscle acts as a bow-string on a broken bow, and forces both of the bones upwards against the skin and out of line. The difficulty in fracture of both bones consists in keeping both these oblique fractures down in place. The skin is extremely thin, and liable to be irritated and to slough unless very carefully treated. Great shortening does not take place in fractures of the lower leg. It is usually not noticed by the patient afterwards; and does not occur to any great degree. Moderate shortening, perhaps, always occurs. It is best detected by setting the patient square on a chair, with the knees at right-angles; feet naked, and toes carefully placed together. In that position we can detect whether one knee is on a higher level than the other.

The difficulty in treatment is principally in getting this oblique fragment of the tibia down in place and keeping it there. Sometimes we can do this with gentle compression and bandage; sometimes by a lateral splint holding the parts. Sometimes we are obliged to raise the heel and the foot in order to draw the lower fragment up into contact with the obstinately riding-up upper sharp piece, which threatens to break through the skin of the leg.

There do exist, occasionally, very irregular and oblique fractures of the tibia which have a split running up the bone besides, in a triangular direction. These are extremely troublesome. They are among the most painful that exist; and the patient suffers from neuralgic pain later. You must warn the patient that such a fracture will repair, in time; but that he will have lameness and pain for a good while afterwards.

Four to six weeks for fracture of both bones of the lower leg; and plaster after that put on for some time, and crutches. Weight put on the feet slowly afterwards.

Pott's Fracture. — The most troublesome fracture of both bones of the lower leg is Pott's fracture; described by Mr. Pott, who was himself a victim of the accident and who devised means of treating it. It consists of fracture of the fibula at the classical place, one to one and a half inches above the joint; rupture of the internal lateral ligament alone, or rupture of the internal lateral ligament with breaking off of the tip of the inner malleolus as well. So that the tibia projects inwards and the foot is dislocated outwards at an angle from the leg.

Now it is very plain what we want to do in order to get this back into place, and if we can accomplish this it can be successfully treated. The dislocation is to be reduced by carrying the foot in. The foot is to be set at a right-angle to the leg so that the lower surface of the foot is at a right-angle with the tibia; the great toe on a line with the inner border of the patella. It is desirable in setting this fracture with

dislocation outwards, to carry the great toe a little further inwards than the inner border of the patella; and instead of having the foot dislocated outwards, have it turn a little inwards, in the opposite direction, as if the patient had a commencing varus. We do not expect to maintain that position always; but we exaggerate a little in order to retain enough of the right position when the foot comes out of the splint. There are some cases of this fracture where the parts will not stay in place; where dislocation backwards occurs; where the astragalus pushes out in front of the tibia; and it is in this class of cases that we are to do tenotomy of the tendo Achillis. Cut that, and the whole thing is in place at once. The proper position is with the great toe a little further in than the inner border of the patella, and the sole of the foot strictly at right angles with the limb. It is best confined with a plaster-of-Paris bandage. The dorsum of the foot and the front of the leg should be left open, so that we can see the position and guard against swelling.

This is a tedious fracture to treat. It takes eight weeks; and you must warn the patient that he will be extremely fortunate if he gets through without stiffness of the ankle-joint, since he has had dislocation and fracture into the joint.

I cannot too strongly call your attention to the fact that in treating all fractures of the lower leg it is of the last importance that the foot should be kept up at right angles to the leg. If we allow the foot to droop, the result is that the bones are so much shortened that the patient walks ever afterward in the position of talipes equinus, on the ball of the foot; and cannot get the heel down to the ground; whereas if from the first he is treated in the rectangular position, subsequently there is no trouble.

Fracture of the Os Calcis. — Fracture of the os calcis is rare. It happens from the person's stepping off a height and lighting on the arch of the foot. If the os calcis is broken off, you can see what must happen. The tendo Achillis, all the strong calf muscles of the leg being inserted there, pulls the large fragment up on the back of the leg.

In order to approximate the fragments of the bone, we have got to put the leg strictly in the equinus position; drawing the heel up as far as possible with a strap, in order to get the fragments together.

Union generally takes place and the result is fairly good.

Fractures of the Tarsus. — Fractures of the tarsus are almost always compound, the result of crushing; or if not, they do not occasion much displacement, and readily heal.

Fractures of the Metatarsal Bones. — Fractures of the metatarsal bones, on the other hand, are frequently produced as simple fractures by the fall of timber on the foot; and give rise to the same sort of displacements and deformities that occur in the metacarpal bones of the hand. Fracture of the metatarsal bones corresponds very much to the fracture of the metacarpal bones. The bones should be held nicely in splints and carefully padded. If subsequent irregularity in the union occurs; and there is any knob or projection above, or below, or at the side of the metacarpal bones, the patient is sure to feel it. Careful attention must be given to the setting and adjustment of bones; and so also with the toes, as with the fingers.

The only point of any importance is this; when you have to treat fractures of the metatarsal bones, the foot does much better upon a large splint shaped like the leather sole of a shoe than upon any narrow splint, fitted on any one individual toe; you want a large wooden sole; adjust it with other splints, plaster or what not, in order to compress the parts into shape.

TUBERCULOUS PLEURISY.[1]

The Shattuck Lecture for 1893.

by WILLIAM OSLER, M.D.,
Professor of Medicine in Johns Hopkins Hospital, Baltimore.

(Concluded from No. 5, p. 114.)

Case XV. Pleuro-peritoneal tuberculosis in chronic pulmonary tuberculosis (abstract).

D. W., aged eighteen, colored, admitted November 21, 1889, complaining of cough, fever, and pain in the abdomen. About two months before admission he was wrecked and exposed in a boat for twenty-four hours. He dates his illness from this time. He can give no details as to his family history. He had syphilis in the spring of 1889. The patient was a medium-sized, fairly well nourished young man, and at the first examination there were signs of disease at both apices, most marked at the right. There was high fever, and very rapid extension of the pulmonary disease, a large excavation developing within a few weeks at the top of the right lung. There were friction sounds heard in the axillary regions, and particularly marked on the left side. The abdomen was full and distended, sometimes painful, and he had diarrhœa. The patient did not improve in any way, but the fever persisted, and he became greatly emaciated, progressively weaker, and died January 25th.

Autopsy. Anterior mediastinal glands caseous. Both lungs were bound down by firm adhesions. The pleural membranes thickened; the costal layer, easily stripped off, was covered with fibrinous exudate, beneath which were numerous tubercles and caseous masses. On the pulmonary pleura there were numerous tubercles and flat caseous areas. Both lungs showed large cavities at the apices, numerous caseous areas, and miliary tubercles disseminated and in groups.

There was only a small amount of clear fluid in the peritoneum; the intestines were agglutinated, and on the peritoneal surface many groups of tubercles and flat caseous masses. The mesenteric glands were greatly enlarged and caseous. There were numerous tuberculous ulcers throughout the entire intestine, beginning just beyond the pylorus and extending to the rectum. There was tuberculous ulceration of the bladder.

We have many opportunites of seeing slight extension of the disease through the diaphragm, either downward from the pleura, or more often from the peritoneum into one or other pleura. In the following case there was extension from the right pleura to the under surface of the diaphragm, and to the peritoneum covering the liver.

Case XVI. Pulmonary tuberculosis; chronic tuberculous pleurisy; tuberculous peri-hepatitis; circumscribed tuberculous peritonitis (abstract).

A. F., female, aged nineteen, admitted June 6, 1892, complaining of shortness of breath. She had been in failing health ever since the birth of her child March

[1] Delivered before the Massachusetts Medical Society, June 13, 1893.

19, 1892, when she had a severe cough, which has persisted ever since. She was pale, emaciated; respirations 44; pulse 148. There was deficient expansion at the right apex and signs of commencing cavity. She was in hospital during July and August, and signs of extensive pleurisy developed on the right side, for which she was aspirated and seven and a half litres of serous fluid removed. She had marked hectic fever. The pleural symptoms were complicated by the presence of a large abscess in Scarpa's triangle, which was opened and drained. She died September 12th of hæmoptysis.

Autopsy. In the anterior mediastinum there were miliary tubercles and caseous masses; both pleural sacs obliterated. The parietal layer of the pericardium, adherent to the pleura, presented numerous fresh gelatinous-looking tubercles. The lungs and visceral pleura on the left side removed together. The layers were greatly thickened, and were covered with a hæmorrhagic, rough exudate one to two millimetres in thickness. The right pleural sac also obliterated, and the membranes united by old adhesions; no acute pleurisy. Throughout the left lung there were several cavities; one at the apex, nine centimetres, and in this there was a ruptured aneurismal dilatation of a branch of the pulmonary artery.

The under surface of the diaphragm on the right side was adherent strongly to the liver and covered with numerous gray tubercules, which were also present in numbers on the upper surface of the liver, and there were numerous hæmorrhages about them.

There was tuberculous disease of the lumbar vertebræ. The mesenteric glands were enlarged, but not caseous. There were tuberculous ulcers in the ileum.

Attention has often been called to the frequent association of tuberculous pericarditis with tuberculous pleurisy. Thus of seventeen cases which I recently described[3] there was combined disease of these membranes in Cases IV, VII and XV. In the following case the pericarditis in all probability followed the chronic tuberculous pleurisy.

Case XVII. Chronic tuberculous pleurisy on the left side; acute tuberculous pericarditis and pleuritis dextra.

John P., aged thirty-eight years, admitted August 18th, with swelling of the legs and dyspnœa. The family history is good. He has been, as a rule, healthy, though in his childhood and youth he had many of the infectious diseases. He has been a moderate drinker. He denies syphilis. The present illness began about two weeks ago with pain in the left shoulder and about the heart. Feet began to swell ten days ago, and he has had cough and shortness of breath for about the same length of time. He has had no nausea; his appetite has been fairly good. Within the past few days he has become much worse.

On admission the patient had intense orthopnœa; pulse 130, but moderately full. He had a distressing cough, with clear watery expectoration. There was great œdema of the lower extremities and of the scrotum. The finger-tips and mucous membranes were bluish in color. In the examination of the heart at the time no murmur could be detected, but the second sound was accentuated at the pulmonary cartilage.

On the following morning the patient was quiet; respirations 28 to the minute; pulse 84, the beats irregular both in rhythm and force, the volume fair, and tension not diminished.

Thorax apparently symmetrical, but the manubrium very prominent, expansion equal. In front, resonance on both sides good, though on the left side flatness begins at the fifth rib midway between the nipple and axillary line, and the dulness seems here to be somewhat movable. There are numerous sibilant and sonorous râles to be heard in front. Passing down the left side and into the axilla, the breath sounds become more feeble and fine moist râles are heard. Pitch of resonance of the extreme left base is higher than at the right, and the vocal resonance is somewhat diminished.

On auscultation there are numerous coarse and medium fine râles to be heard at both bases. At the extreme left base the respiratory murmur is almost absent.

Heart: Point of maximum impulse difficult to localize; slight general heaving over the whole præcordial area; relative dulness begins above at second rib and extends well to the right of the sternum. The prominence above noted is just at the junction of the manubrium and gladiolus, and just at this point there is dulness over a very limited area. Relative dulness extends outward to a point nearly five centimetres outside the nipple. The heart-sounds are heard with the greatest intensity at the fifth space a little inside of the nipple line. There the first sound is full and booming; the second not so loud. Passing inward toward the sternum the sounds become associated with a superficial, soft, squeaking sound, diastolic in time, heard loudest over the mid-sternum, and pericardial in character. This is heard faintly all over the base. The murmur is more distinct in forced expiration than during inspiration. The second pulmonic is a trifle louder than the second aortic sound. The radial pulses are equal in volume, and there is no pulsation in the upper sternal notch; there is no tracheal tugging. The examination of the abdominal organs is negative. The urine is yellow-colored, acid, specific gravity 1024, distinct trace of albumin; several hyaline casts were found. Throughout the 20th and 21st the patient remained in much the same condition. On the 22d there was a slight rise in temperature to 100.5°; the pulse varied greatly in rate and character; at noon was slow, regular and full, from 70 to 90 per minute, and again was as rapid as 140. The patient, in many respects, was better. The œdema of the legs had disappeared. The urine had increased in quantity. On the 19th only 180 c. c., and on the 20th 350 c. c. had been passed. On the 21st and 22d the amounts were 700 and 1100 c. c.

August 23d. The temperature has been between 97° and 98°; at the morning visit the pulse was 148, regular in force and rhythm; the respirations 32. The patient was lying quietly on left side. The physical signs practically those noted above, with the exception that there is an extension of the œdema at the base of the lung. The patient died suddenly at 4.30 P. M. to-day.

Autopsy (by Dr. Flexner). Large, muscular man; moderate œdema of the legs and of the subcutaneous tissue of the trunk. Fat well retained, both beneath the skin and in omentum and mesentery.

Pericardium is adherent to the left pleura; the sac thickened and contains a considerable amount of clear serum. Both layers are covered with a thick fibrous

[3] American Journal of the Medical Sciences, January, 1893.

deposit, looking like a hairy coat. The thickness of the pericardium over the heart is 3 mm. When incised the thickened layer is grayish in color, with many opaque or yellowish points scattered here and there, often continuous, and having the well-recognized characteristics of tubercles of this membrane. The heart was greatly enlarged. The valves were normal. The thickness of the left ventricle was 17 mm.; length of ventricle, 8.5 cm.; mitral orifice, 10.5 cm. in circumference. Thickness of right ventricle, 6 mm. Tricuspid orifice, 12 cm. in circumference. The walls of the auricular appendix are almost completely converted into a grayish-white material with only a thin internal film which appears like muscle. In the endocardium of the left ventricle are numerous ecchymoses. There are also a few small ones on the right ventricle and in the auricles, and on the endocardium of the auricles are a few small, round, whitish miliary tubercles.

The left pleura is much thickened; parietal and costal layers adherent in places, but where not in actual contact there is clear serum between them. The costal pleura strips up with difficulty, and is very hard and cuts like cartilage. The diaphragmatic pleura is especially thickened, and on section it is seen to be composed of a dense, almost cartilaginous, grayish tissue, containing yellow, opaque, caseous masses. The apex of the left lung is retracted, hard to the touch, and on section contains a dense, deeply pigmented connective-tissue, and old areas of caseation; no calcification. There are a few small foci of miliary tubercles, and scattered fibrous tubercles elsewhere in the lung.

The right lung is voluminous, and in the greater part of its extent free from adhesions, but the pleural surfaces present numerous grayish-white elevated masses, single and conglomerate, which can be scraped off with difficulty. The costal pleura present similar tubercles. About these there are, here and there, fresh fibrin. In the apex, the upper lobe presents a few foci of fibrous miliary tubercles.

The spleen contains a few scattered tubercles. Nothing of note in the abdominal viscera; the intestines did not present tubercles.

III. GENERAL PATHOLOGY.

The pathology of serous membrane tuberculosis turns on the avenues of infection rather than upon any special peculiarity in the lesions. Miliary tubercles, with inflammatory exudate, serous or hæmorrhagic; acute, rapidly caseating and ulcerative processes with necrosis and suppuration; a chronic fibro-tubercle, nodular and diffuse, are here met with as in the lungs and elsewhere — and the chief interest relates to the

Avenues of Infection.

(1) Doubtless a great majority of all cases of tuberculous pleurisy arise from direct infection from the lung, a tuberculous focus invading the membrane, as may be seen any day in the autopsy-room. Rapid development of a fibrinous exudate at the spot controls the extension, blocking the lines of transmission and limiting the process. Though directly excited by contiguity, the pleurisy is not always associated with an eruption of miliary granules, but may be simple. There would appear sometimes to be an antagonism between the pleural and pulmonary disease, and it will have been noted in several of the post-mortems of the cases previously given that very extensive affection of the pleura occurs with very slight or even without any disease of the lung on the side involved. The possibility of infection of the pleura by contact from tuberculosis of the mediastinum, tuberculous abscess of this part, and, indeed, from cold abscess of the thoracic wall, must also be considered.

(2) Infection through the lymphatics. It was one of the great generalizations of Bichat when he spoke of the serous membranes as "grands reservoirs," a truth demonstrated by the intimate connection known to exist between these surfaces and the subjacent lymph vessels. The beautiful investigations of Klein, Arnold, and others, have taught us the complicated anatomy of the lymph apparatus of the lungs and pleura, and also the course of the lymph streams, so that it is not difficult to understand how the serous membrane may be affected. We all inhale tubercle bacilli, perhaps not daily, but dwellers in cities and workers in hospital wards certainly inhale them very frequently, attached to the dust particles, the fate of which in the respiratory system is well known. A certain proportion in the trachea and bronchi are dealt with by the leucocytes, and are brushed by the cilia to the larynx: the sweepings of the night appear in the dark morning expectoration. Many of the particles reach the alveoli, and are here also in part attacked by the large desquamating cells of the alveolar epithelium, an important function of which is, no doubt, to help in the general scavenger work which goes on incessantly in the lungs. But a considerable number escape the phagocytes of the bronchial tree and of the alveoli, and pass through the openings in the latter into the alveolar stroma. Those from the air-cells enter the deeper lymph channels which surround the bronchi, and in their course pass through many of the lymph nodes, at every one of which they are attacked, and many of the particles remain fixed in the cells of the follicular cords or permanently imbedded in the stroma. Those particles which reach the more superficial alveoli pass into the wide sub-pleural lymph streams. Here, too, at the periphery of the lobules, as may be seen in the lung of any adult, many of the dust particles are picked out and fixed in the perilobular tissue, so that often the lobules are accurately mapped out by a line of black particles. Ultimately, a certain number reach the bronchial glands, which become gradually in all of us, as the years pass, more and more deeply pigmented. The tubercle bacilli attached to the dust particles follow these routes, and their fate depends very much upon the local conditions, which, happily for the majority of us, are not favorable to their growth. It is interesting to note, however, with reference to the mode of infection in tuberculosis, the large proportion of individuals in whose *dust-filters*, as the lymph nodes of the respiratory system may be called, tubercle bacilli effect a lodgement. Indeed, there have been important observations within the past few years to show that the bacilli may be present (without having caused any mischief) in apparently healthy lymph glands. There is direct communication between the sub-pleural lymphatics and the sac of the pleura, so that it is possible to conceive of a direct entrance of the bacilli in that way. More commonly, however, the disease spreads from a sub-pleural nodule or a lymph node in which the bacilli have grown. The wide and free anastamoses which have been demonstrated to exist in the lymph vessels of the pulmonary pleura favor the rapid diffusion of the virus under suitable conditions. Possibly, too, in

some instances, direct infection may take place from the bronchial and tracheal lymph glands. Under all these circumstances it is the visceral layer of the pleura which is involved. The lymphatics of the parietal pleura have wide and extensive communications, discharging as they do partly into the lymph glands along the vertebræ, and partly in the anterior mediastinal group, along the internal mammary artery. Infection may come from the lymphatic glands in the neck, particularly the supra-clavicular, which communicate freely with those of the axilla and of the sub-maxilla. Infection of the pleura in tuberculosis of the glands in these two groups, has been frequently noted, and has been made the subject of a special essay by Hernandez.

In rare instances the disease may extend to the pleura from tuberculous caries of the bones in the neighborhood. An interesting instance of this was reported to the Johns Hopkins Hospital Medical Society by Dr. Flexner last winter. A colored man, aged twenty-four, had a sinus in the neck which led to an erosion, involving the outer third of the right clavicle. The supra-clavicular glands in the neighborhood were involved, particularly the group between the clavicle and the upper border of the pleura, which were enlarged and caseous. The right costal pleura was greatly thickened, firmly united to the visceral layer, except on the diaphragmatic surface on which there was a cavity the size of an orange filled with a sero-fibrinous exudate.

And lastly, the pleura may be infected through the wide communications which exist between the lymphatics of the peritoneum and those of the diaphragmatic pleura, and the lymphatics of the mediastinum.

IV. DIAGNOSIS.

A disease presenting clinical variations so extreme as those which I have attempted to portray must necessarily offer at times serious difficulties in its detection. At the outset, it may be frankly acknowledged that often in cases of acute sero-fibrinous pleurisy, coming on with chills and fever and gradual effusion, we have not the data upon which to base a diagnosis. Neither the appearance of the individual, the family history, the onset, the course, or the character of the exudate may be in any way suggestive. On the one hand, there can be no question that many instances, as in Case I, so often referred to, occur in robust individuals of previous good health, with all the characters of pleurisy *a frigore;* and yet the subsequent history may point very clearly to the fact that the process has been from the outset tuberculous. On the other hand, the view which has of late found so much favor, that a large proportion of all acute pleurisies are tuberculous, is certainly unfounded, as shown by the post-mortem notes already referred to, in which non-tuberculous pleurisy of one form or another was present in two-thirds of an unselected series of cases from medical wards. I have already called attention to the points to be specially investigated; the antecedents, family and personal, the careful inspection of the groups of lymph glands contiguous to the pleura, the repeated examination of the expectoration, which may contain tubercle bacilli from even a very small focus of softening tubercle in communication with the bronchus. On more than one occasion it has happened that their discovery after repeated examination has cleared up the nature of an obscure pleurisy; and it is worth noting that in Case I the only spot of softening from which the tubercle bacilli could have come in any numbers did not exceed the size of a hazelnut, and was in the lung on the side opposite to that of the effusion. The physical characters of the exudate offer in a majority of instances nothing distinctive. A hæmorrhagic exudation is suggestive but by no means distinctive, inasmuch as it may occur in cancer, or it may occur with ordinary simple pleurisy, as in two instances in our list. It is important to note that the effusion may be hæmorrhagic in either a chronic or in an acute form. I call to mind one instance in which the presence of hæmorrhagic exudate led us to suspect a terminal tuberculous pleurisy, but there were no tubercles on the membranes.

The bacteriological examination has been made now so frequently in acute pleurisies that there are facts enough at our disposal to warrant a somewhat definite opinion, and the general conclusion is that, except in very rare instances, the serous exudates are sterile, and tubercle bacilli have only been detected in a very moderate number, in only 32 cases, according to the recent article of Prince Ludwig Ferdinand of Bavaria. The inoculation of the exudate into the peritoneum of the guinea-pig, which has been practised in many cases, also gives variable results, but when positive is of great value.

The inoculation with tuberculin is, as mentioned, uncertain, and I may state here an instance in which it led us into error. Just as we were beginning to try it the late Dr. Christopher Johnston sent into the wards a young woman aged about twenty-eight or twenty-nine with a bunch of enlarged lymph glands on the left side of the neck and the axilla. She was fairly well nourished and made no other complaint but of gradual and progressive enlargement of these groups during several months. Within ten days or two weeks after admission a pleurisy developed on the same side, which we very naturally thought to be tuberculous. She was treated with injections, and the reaction on each occasion was particularly active. No benefit, however, followed them, and some weeks later she went to her home, where she shortly afterwards died. The autopsy, performed by Dr. Councilman, showed cancerous lymph glands in the sub-clavicular and axillary regions and extensive cancerous pleurisy — the primary disease being a nodule of carcinoma about the size of a walnut in the left breast. Some months subsequently, in illustration of the curious coincidences which we all meet in practice, I saw a case presenting striking similarities in the practice of Dr. Burns, of Toronto, also in a comparatively young woman, but the infiltration about the pectoral muscle called my attention to the condition of the breast.

The diagnosis of the purulent form of tuberculous pleurisy is less difficult. A proportion of these, at least 75 per cent., depend upon infection with streptococci, the pneumococci, or the staphylococci. The tubercle bacillus may be present and in some acute cases, as in the one referred to, very abundant in the pus. In other instances, definitely proved to be tuberculous, staphylococci have been present, and sometimes the effusion is sterile. The course may be extremely suggestive, and it has long been known that the latent variety of empyema is not uncommonly tuberculous. As already mentioned, the fluid may not be truly purulent, but the turbidity due to the presence of large quantities of fatty material.

And lastly, a great difficulty in diagnosis may exist in these cases of sero-fibrinous pleurisy which recover with thickening of the membranes and persistence of flatness at the base. The most suspicious instances are those in which the fluid constantly recurs in spite of repeated tappings, and in which, with diminution apparently in the amount of exudate, the flatness persists, usually with transmission of the tactile fremitus, and sometimes, as time proceeds, marked flattening of the affected side. The records of Cases I, IX and XI show a sequence of events only too common. Possibly some of these cases, with flattening at the base and slight retraction, heal, and no further trouble occurs. Certainly they are not always tuberculous, such a process may follow a simple sero-fibrinous pleurisy or an empyema. Thus in a young woman aged twenty-three, who was admitted to my wards November 17, 1890, with the right chest flattened behind and at the sides, with dulness at the right base and curvature of the spine (and who died of anæmia associated with syphilis of the liver, and lymphatic nodules), the right lung was firmly adherent, the pleural membranes were thickened, particularly at the extreme base, and between the thickened layers there was a cavity containing about 70 c. c. of an opaque, whitish fluid. The cavity presented adherent calcareous flakes, and there was no caseation. Such instances are by no means uncommon in post-mortem work, and unquestionably contraction and flattening at the base and slight drooping of the shoulder may persist for an indefinite number of years without leading to any more damage than perhaps a progressive bronchiectasis in the lower lobe. Clinically, too, these cases are not very infrequent, and though one may have a suspicion from the history, yet good health may be maintained for many years and evidence may be entirely wanting of any tuberculous process.

V. TREATMENT.

The indications are twofold: first, to limit and control the exudate and to promote its absorption. It would take me far away from the immediate subject to discuss here in full the therapeutics of pleural effusion. In the early stage it is sufficient to allay the pain, if severe, with opium, to reduce the fever, if high, by sponging, and to keep the bowels freely opened. It is doubtful whether the salicylates deserve the confidence which many claim. To promote absorption various measures are advised. It is important to remember that when fluid remains in the chest it is for the very good reason that it cannot get out, owing to blocking of the lymph paths. Absorption from the pleura goes on, as has been shown experimentally, with extraordinary rapidity, chiefly, if not entirely, from the costal layer. Probably in all instances of pleurisy with effusion, do what we may, the absorption has to wait the freeing of the obstructed lymph channels. I still believe that good results are seen by putting the patient on a dry diet and giving brisk, saline cathartics. It is a rational practice, and in some instances I have seen the exudate diminish rapidly. The diuretin, when it acts, is useful in the same way. If at the end of ten days the exudate persists, and is at the level of the fourth rib in the erect posture, aspiration is advisable, and it may be repeated again in a few days if the fluid reaccumulates. So far as I know, there are no greater risks in the tuberculous than in the simple sero-fibrinous cases, and it is very important to relieve the lung early of the compression to which it is subjected by any large quantity of fluid. I think, however, the risk of the compressed lung becoming the seat of tuberculosis is not very great; more serious is the danger lest it should become bound down by such firm adhesions that it cannot expand. Gentle counter-irritation of the skin is probably beneficial in these later stages, stimulating the lymphatics of the costal pleura.[4] In the cases of chronic sero-fibrinous effusion with thickening of the membranes the fluid reaccumulates rapidly, and aspiration may have to be performed very many times. In these instances systematic pulmonary gymnastics should be practised. The expansive efforts of forcing water from one large Wolff's bottle to another is a good method. When the exudate is purulent the case should be transferred to the surgeon for thorough drainage.

The second indication is to improve in every way possible the general nutrition of the patient, so as to favor conditions promoting the healing of the tuberculous process. No doubt, as in pulmonary and peritoneal infection, many instances of tuberculosis of the pleura recover and leave no more damage than that associated with slight thickening of the membrane. A life in the open air, regular habits and exercise, a nutritious diet, and the use of the remedies which promote in every way digestion and the assimilation of food should be advised. And finally we may lay to heart the words of Sir Andrew Clark: "When we have a patient with basic fibrinous pleurisy, let us hold him fast, restrict his freedom and treat him carefully until every remnant of it is gone."

THE TREATMENT OF PNEUMONIA.[1]

BY F. C. SHATTUCK, M.D., OF BOSTON.

TWENTY years ago the profession generally held that croupous pneumonia is rarely fatal, except in the aged or in those whose constitutions are weakened by alcoholic or other excess. At that time the doctrine that the disease is a local inflammation of the lung, to which the general disturbance is secondary, was just beginning to give way to the view that the lung process bears much the same relation to pneumonia that the affection of Peyer's patches does to enteric fever. At present there seems to be a disposition on the part of some to return to the local disease doctrine, though, of course, in a different form, and to class pneumonia with diphtheria and erysipelas.

To-day there is certainly a dread of pneumonia among the laity, and, I think, the profession feels less confidence in the power of youth and vigor to withstand the disease than it formerly did. Has pneumonia changed its type in the last fifty or in the last five years? Has the resistance of the population diminished? These are questions which have been often asked. That which first led to their asking was the revolution in treatment, and particularly the abandon-

[1] Read before the Massachusetts Medical Society, June 13, 1893.

[4] The relation between the subcutaneous and pleural lymphatics must be very close. A fluid containing colored particles in suspension, injected beneath the skin in the axillary region of a rabbit, finds its way to the costal lymphatics, and the anterior mediastinal glands become stained. (Canada Medical and Surgical Journal, 1875. Article on Anthracosis.)

ment of venesection. We wonder how our predecessors could have bled, purged and puked patients whose every scrap of strength we seek to save. But they also treated consumption antiphlogistically. As far as we can reason from analogy it does not seem probable that the disease has permanently changed character. We do not think that other specific diseases have so changed in this period. If they have changed at all they have become less rather than more fatal.

The valuable paper of Townsend and Coolidge [2] shows that in the Massachusetts General Hospital there has been a marked increase in the mortality from pneumonia; but that this increase, when carefully studied, cannot be attributed to the change in treatment, and probably not to any change in the disease itself.

It seems to me that factors which are very important, but which do not easily lend themselves to statistical inquiry, are the great change in the character of the population, or perhaps still greater change in its manner of life, both poverty and luxury having greatly increased; and the wear and tear of the nervous system incident to modern commercial and domestic methods, which has been multiplied many fold. Cities have grown large. The very poor have a better water now than many of the well-to-do had in the days of contiguous wells and privies. But it is far otherwise with the air, whether in or outside the house. I must not, however, pursue these questions further, though they have an obvious bearing on therapeutics and its results. And I can only allude to the influence of grippe on pneumonia. The former seems to prepare the way for the latter only indirectly by lowering the resisting power. Influenza thus renders a person more liable to pneumonia, and also probably diminishes his chances of recovery.

Pathology and therapeutics do not always go hand in hand. In some diseases our pathology is ahead of our therapeutics: in others the reverse holds true. We began to treat pneumonia as a general disease before we knew it to be such, and we were convinced that it must be such before we knew of the existence of the diplococcus or toxines and anti-toxines.

The fruit of bacteriological discovery is not yet ripened, though, as we shall see later, there is reason to hope that ripening may be in process.

As far as prophylaxis goes we cannot as yet accomplish much. We can caution convalescents from other and milder affections, especially during the season to which experience shows us pneumonia is most incident. We can warn our patients at these seasons not to treat lightly severe colds. We can "preach the gospel of hygienic righteousness," as the late Dr. George Derby put it.

No method of aborting the disease which has yet been proposed has made good its claims. Pneumonia, like typhoid fever, may abort spontaneously. But we cannot make it do so. Still, it seems to me that the method of Pétresco, of Bucharest,[3] is worthy of trial. Since 1883 he has treated 755 cases of pneumonia with very large doses of digitalis from the time they first came under observation. He gives for two or three days a strong infusion, and claims to be able to cut early cases short, and to influence very favorably more advanced cases. His mortality now is only 1.22 per cent. He gives from one to two drachms of the leaves daily, the equivalent of one to two ounces of our tincture. In like manner we have had no distinctly curative treatment, though we are encouraged to hope that the injection of immune blood serum may prove to be such after further trial. In short, our efforts are at present confined to promoting the comfort of the patient, and conserving his forces in every way to enable him to outlive the self-limited disease. This in itself may be much.

For the better application of this general principle it will be more convenient to divide the disease into stages, remembering always that these divisions are arbitrary, and that nature does not seem to feel herself bound strictly to abide by them. Patients very rarely succumb to the stage of invasion or preliminary congestion of the lung with active implication of the pleura. The danger here is not of dying; it is rather of loss of strength, which may be sorely needed later. The indication, therefore, in the ordinary case is to relieve the pain, to put the patient to bed and freely open the bowels, just as the mariner prepares his ship for an impending hurricane. The severity of the pain and any known or ascertainable peculiarity of the patient will decide the character and amount of the means for its relief. In the early days, at least, there can be no question of the safety of morphine, which should be used freely and frequently, hypodermically. Restlessness and an excited nervous system call for morphia nearly as loudly as does pain. Dyspnœa in the average case is at this stage due far more to the pleuritic pain than to the state of the lung, But now and and then we see a case in which so much lung tissue is so rapidly invaded that the heart finds it difficult to adjust itself to the changed condition, and greatly oppressed breathing results. In such a case nothing gives such prompt relief as venesection, the freedom of which is to be proportioned to the age and vigor of the patient and its effect on the symptoms. With the veratrum viride treatment of the Philadelphia school I have no personal experience. If internal antipyretics are to be used at all in pneumonia it is only during the first stage that they are admissible. I am no friend of them myself, and never use them in this disease. Even the best of them is somewhat depressing to the heart.

During the prevalence of the old doctrine of the nature of pneumonia and of inflammation, treatment was naturally addressed to the diseased organ, and antiphlogistics were used externally and internally. We now recognize the fact — or believe it to be a fact — that the cause of death in the second stage is rarely asphyxia as a result of the amount of lung involved. The loss of function of a portion of the lung plays in most cases a rôle which is quite subordinate to that of cardiac exhaustion, dependent probably on the influence of toxines on the innervation of the heart rather than on changes in the myocardium. That it is mainly a toxæmia which weakens the heart and not simply the mechanically increased resistance in the right chambers, seems to be proved by the great fall in the pulse, as well as the breathing, coincident with crisis, although the physical signs over the affected lung area may show no appreciable change.

It is then the maintenance of nerve force which we must try to secure. This means the avoidance of every unnecessary fatigue and the administration of the largest amount of the most nutritious liquid food which can be digested, with free ventilation of the apart-

[2] Transactions of the American Climatological Association, 1889.
[3] Bull. de Thérapeutique, 1892, p. 120.

ment. It seems to me that the poultice and the envelopment of the chest in cotton or wool are relics of the old pathology. The poultice is the worse, as its frequent change involves notable fatigue and its weight is not insignificant. I have no experience with the application of ice, which seems to be gaining favor in this country after long use in Germany, to which country we are more apt to look for pathological than for empirical therapeutic suggestion. With regard to food and feeding, I do not propose to go into any detail. But I do want to enter a plea for greater freedom of ventilation than is generally allowed. Here, again, the old pathology seems to me still to influence the medical as well as the lay mind. I am convinced that courage in facing popular prejudice against cold air, and less reverence for the seventieth degree of the thermometer would subserve the interests of our patients and diminish the bills for oxygen. If I should be so unfortunate as to contract pneumonia, I trust that my doctor will put me in a sunny room and give me the benefit of a combination of open fire and open window. It is not pleasant to be accused justly or unjustly of killing our patients, and I must plead guilty, I fear, to a lack of the full courage of my convictions on this point. In the case of a very rich man whom I saw repeatedly in consultation last winter, and who wished no expense to be spared, I soon found that it was useless to try to get a window open. Nor did I succeed in getting even an open fire. But cylinder after cylinder of oxygen was breathed with avidity.

The use of morphia in the first stage has been already touched upon. Experience is leading me to think that it should be used more freely in the second stage than is customary. Here it is not called for by pain so much as by restlessness, cough and sleeplessness. In any given case we must try to estimate the proportion of danger from respiratory failure. The smaller this danger the more freely can we use morphia, which will do more good in resting the nervous system than harm in other ways. And even in cases where the danger of respiratory failure cannot be disregarded, but morphia is indicated on other grounds, I believe that the inhalation of oxygen enables us to give morphia when we might otherwise feel compelled to withhold it. With oxygen, of late years, I have had considerable experience. I have seen it given freely, and without regard to expense. But I can recall only one case in which I feel reasonably convinced that it saved life — that of a Harvard student whom I saw with Dr. Hildreth. Even here we had to deal with a patient whose age should have ensured his recovery according to the books. In many cases I have seen it give marked relief. Our experience with this gas is now sufficient to enable us to estimate its value better, and to use it more intelligently than a few years ago. Physiologists kept it out of use longer than we should have allowed them to do, telling us that the consumption of oxygen is no greater when the pure gas is inhaled than it is under ordinary conditions. Even if this is true of the well, it does not follow that it is also true of the sick. I suppose to-day clinicians are agreed that oxygen may be useful when a sufficient amount of air to arterialize the blood is prevented from reaching the alveoli, a condition which is present in some cases of pneumonia as the result of excessive secretion in the bronchial tubes in combination with the lung consolidation. Cyanosis is, therefore, the best single indication for oxygen. In such cases it should be used early, and as freely as the purse of the patient will allow. Unfortunately, it is still a very expensive remedy. But it is my feeling that its usefulness is wider than would appear from the above. I think I have seen refreshment, quieter respiration, a fuller pulse, and diminished restlessness, perhaps sleep, follow oxygen, even where cyanosis was absent or slight. I have asked myself the question whether the gas may perhaps act as an aid in the combustion of toxines, all compounds of unstable character, I believe. The other chief means of stimulating the flagging heart, as reflected in the pulse and the character of the sounds, are alcohol, strychnia, cocaine, digitalis, and other heart tonics. I shall not delay to speak further of alcohol, as I think we are all pretty well agreed as to its usefulness and the indications for its employment. Strychnia has grown in favor of late years, and I think justly. It is best given hypodermically, and, in severe cases, to the limit of toleration, one-twentieth to one-fortieth of a grain every three or four hours. H. C. Woods speaks highly of cocaine as an adjuvant to strychnia.

All writers advise, and all practitioners use digitalis or one of its congeners, if there are any indications of a failing heart. I have so used it constantly, but must confess that I do not feel perfectly clear as to its usefulness as it is ordinarily given. Perhaps we do not use it in large enough doses. I am sure that we should use it hypodermically more than we do. I have this year seen prompt and distinct effect in several cases follow hypodermics of thirty minims of the tincture. Pétresco's results are confirmatory of the idea that our doses of digitalis are often insufficient. An editorial writer in the *Therapeutic Gazette*, in 1892, in speaking of Pétresco's paper, which he evidently did not read with care, thinks that pneumonia must be a different disease in Roumania from that which we see, and that the digitalis must be of poor quality. The first supposition is highly improbable, and Pétresco has anticipated and answered the second. He notes repeatedly a pulse-rate of 36 to 48 within thirty-six to seventy-two hours after the digitalis is begun, and has supplied himself from the best houses in Paris and Berlin as well as from native sources.

With the cold bath and cold wet pack as remedies against high fever, delirium and other nervous symptoms, I have but slight personal acquaintance. A period of the disease which we all recognize as one of much danger in some cases is that immediately following the crisis. Exhaustion or collapse at this time calls for rapid stimulation; alcohol and ammonia internally, heat to the surface, brandy and ether under the skin.

In cases terminating by lysis, and in delayed resolution, a supporting treatment is to be carried out according to the indications presented by the case in hand. The frequency of empyema as a sequel to pneumonia, is never to be forgotten, if for no other than a therapeutic reason.

Lépine[4] has recently employed with success injections into the thighs or arms of oil of turpentine, when he feared that gray was passing over into yellow hepatization. Fochier first suggested and practised this method in puerperal septicæmia, having noticed that improvement took place when a focus of pus was established. The turpentine produces an abscess — "of fixation," Fochier terms it — which can be opened

[4] La Semaine Médicale, 1892, p. 77.

later. Dieulafoy and Bard [5] have each practised this method in pneumonia, with recovery in both cases. Others in France have also used it a few times, but I have not been able to get access to the journals in which the reports appeared.

In three desperate cases in my service at the Massachusetts Hospital, this winter, I had turpentine injected, in one case on the ninth, in two on the seventh day of the disease. All three died, as seemed certain that they would, whatever was done or not done. I do not think that these cases should really count for, or against the method.

For therapeutic purposes cases of pneumonia may be divided into three classes. First in frequency are those cases which will recover under any treatment or no treatment, unless they are grossly mismanaged; second, those which will die in spite of any and all treatment known at present; third, those in which judicious treatment may turn the scale.

Our object is constantly to strive to enlarge the third class at the expense of the second. Thus far, our efforts have been unsuccessful enough, it must be admitted. But, however sceptical we may be, we should not be hopeless, or refuse to listen to those who bring forward new methods, with an underlying basis of reason and fact. One method of curative treatment has been recently introduced which can claim an encouraging though limited success in practice, as well as foundation in analogy — with tetanus, for instance. Only one case has been reported thus treated in this country, but it would seem our duty to lose no further time, and I propose to test the method in my wards next autumn and winter.

I refer to the injection of blood serum from a human being who has recently passed the crisis of pneumonia, or blood serum or fluid derived from animals rendered immune to experimental pneumonia by the injection of pneumococcus cultures. I will not take your time by going into the details of this method and its technique. The articles of the Klemperers,[6] and others in Germany and Italy who have tried it, are accessible enough. Suffice it to say that the purpose is to induce the crisis artificially, and that of thirty-nine cases thus treated, collected for me from literature by Dr. R. C. Cabot, all save one recovered. Whether the pneumotoxin and antipneumotoxin theory of its mode of action is final or not, remains to be seen. In the sole American case [7] defibrinated blood was used, with results which do not encourage a second trial.

THE RELATION OF HOSPITALS TO MEDICAL EDUCATION.[1]

BY HENRY M. HURD, M.D.,
Superintendent of the Johns Hopkins Hospital.

It is not my purpose to argue the duty of hospitals to promote medical teaching. They have always contributed to it and always will, in an increasing degree, as medical education becomes better organized and more efficient. The hospital, whether avowedly so or not, has always been a school of medicine, sometimes to the few who were attending physicians, resident physicians or internes, and sometimes and now, I am glad to say, more often to those who are pursuing medical studies. The relation of hospitals to medical education has been reciprocal for good. Medical teaching has improved hospital work and hospital work, on the other hand, has improved medical teaching. Neither can exist without the other. It is my purpose, in this brief paper, to point out methods whereby hospitals can best subserve medical teaching and to emphasize the duty of promoting it. A hospital which does not contribute to the advancement of medical knowledge by bringing the results of its investigations and experience to the training of medical students in the plastic stage of their education, fails to attain its highest good or to surround itself with the brightest investigators. The duty being apparent, to point out the best method of attaining the desired end must be the sole object of the present inquiry.

(1) *Pathological Institutes.* — First in importance I would place the organization of a good pathological institute in connection with every hospital. By this I mean much more than an autopsy room and a museum for the preservation of morbid specimens. These are valuable, but their work is not of prime importance compared with what may be accomplished by systematic investigations in all branches of pathological study. Facilities should be afforded for the study of every morbid product. There should be opportunities for systematic bacteriological examination of pus, serous effusions, the products of inflammation, the bodily secretions and excretions, false membranes, new growths and the like. The diagnosis of diphtheria and of follicular tonsillitis, for example, should here be made by cultures, cover-slip preparations and the microscope. The different forms of peritonitis should be differentiated similarly. The effusions of pleurisy should be studied bacteriologically to determine the presence or absence of the tubercle bacillus. Malarial fever should be differentiated from other forms of continued fever by the presence of the plasmodium. The micrococcus lanceolatus, otherwise known as the pneumococcus, should be searched for in pneumonia and cerebro-spinal meningitis. Such studies are impossible unless rooms are provided, specially fitted up with apparatus, instruments and trained observers constantly at hand for the purpose. These studies give a definiteness to diagnosis by excluding possible diseases of other origin; and certainty to prognosis.

The microscopic study of tumors and new growths while an operation is in progress and before its completion, is of equal value. Three examples drawn from actual occurrences in a Baltimore hospital, will serve to make my meaning clearer. A patient with a suspicious abdominal tumor, presumably malignant, had submitted to an exploratory operation and a frozen section, while she was on the operating table and before the operation was completed, showed the growth to be tubercular in character. The cavity of the abdomen was drained and washed out with a sterilized salt solution and the patient made a good recovery. A second patient seemed to be suffering from a simple abscess of the breast, but a bacteriological examination of the contents of the abscess cavity showed that the inflammation was tubercular in character and led to the examination of the surrounding tissues, which were found to be filled with tubercle bacilli. A radical operation for the removal of these diseased tissues

[7] Hughes and Carter, Therapeutic Gazette, October, 1892.

then followed and a condition was found present which justified a grave prognosis. In another case a culture made during a severe abdominal operation, subsequently showed that a chronic peritonitis had been caused by a virulent streptococcus and led immediately to the isolation and separate nursing of the patient to prevent the infection of the ward. Such instances are of daily occurrence and the wisdom of these expert examinations is fully established by repeated experience.

In dressings, also, subsequent to surgical operations, similar sources of infection are revealed by bacteriological examinations; and the communication of infection to other patients may be prevented by the knowledge thus acquired. This work, while of prime importance, ought not to impede the true work of a pathological laboratory, which is to study the origin, course and effects of disease upon every organ of the human body. Every large hospital ought to have a paid pathologist, whose whole time should be given to this form of study and he should be provided with a sufficient number of assistants to do this work thoroughly. Diseased tissues and organs should be examined in gross at the autopsy table and afterwards the material should be studied in frozen sections and by hardened specimens. Cultures should also be made post-mortem of all products of inflammation to determine their precise character. These studies clear up obscure diagnoses and lead to the more successful treatment of other cases.

(2) *Clinical Laboratories.* — Every hospital ought also to have a clinical laboratory for blood examination, urinary analysis, the examination of the stomach contents and the examination of fæces and sputum. The blood should be examined, as a matter of routine, in all forms of wasting disease. The value of the methods of Ehrlich in the different forms of leukæmia is attested daily by practical observation. The differentiation of malarial from typhoid or other forms of continued fever, is frequently only possible when the plasmodium has been demonstrated in the blood. The importance of a bacteriological examination of cholera stools for the presence of the comma bacillus, has been recently demonstrated in the late cholera epidemic in Europe. The equal importance of searching dysenteric stools for the presence of amœbæ coli has been demonstrated many times in the Clinical Laboratory of the Johns Hopkins Hospital during the past year. Abscesses in the liver and lungs and one jaw abscess have thus been shown to be dependent upon this protozoan. The confusion which exists in the profession to-day, regarding malarial hæmaturia, can only be cleared up by similar expert examinations. In such clinical laboratories syphilis often needs to be differentiated from tuberculosis by the microscope. Skin affections also, like urticaria, favus, the different forms of dermatitis, tinea versicolor and tuberculosis need to be similarly studied. The presence of the otomycosis aspergillus in ear affections can only be definitely shown by the microscope. The tetanus bacillus, the streptococcus of erysipelas, the staphylococcus of suppuration and the pneumococcus of pneumonia and meningitis should also be similarly demonstrated when present. In no other manner can medical education be made definite and thorough. The day of theories and brilliant hypotheses to account for many of these diseases is past and demonstration ought to replace them.

(3) *Operating Rooms.* — Every hospital of any size, and especially a hospital to which medical students have access, should have surgical operating rooms arranged for carrying out a perfect surgical technique. Here should be consistent and constant efforts to reduce the danger to patients from the infection of wounds to the minimum. These operating rooms should be object lessons in thorough surgical cleanliness. There should be apparatus for hand disinfection and facilities for scrubbing and cleansing the hands. Every step in the technique of antiseptic surgery should be carefully prescribed and followed. It is now evident that infection of wounds does not come through the air or from atmospheric conditions, but rather from actual contact. Pus-producing germs gain access to wounds at the hands of the operator or his assistants or by infected instruments or ligatures or through infected skin-stitches or by subsequent dressings. Hence, it is of the utmost importance that the technique pursued in every hospital operating room be thorough and consistent to the end that every person may know the reason of the procedures adopted. Students and physicians should be trained to appreciate understandingly what is harmful and to be avoided and what is harmless and permissible. It may be asserted with confidence of no successful contradiction that, in the technique of many surgeons, unnecessary precautions are frequently taken and necessary precautions are as frequently omitted from a lack of adequate knowledge of the true sources of infection. These can only be adequately taught by bacteriological methods. Ligatures, instruments, bandages and all forms of dressings should be sterilized in such a way as to meet every bacteriological requirement. Cultures taken from the first dressings, made subsequent to an operation, should not grow upon any form of culture media. Experiments which have been made in wound infection have clearly demonstrated its sources and its methods of prevention. Each operating room should be as carefully arranged to carry out antiseptic precautions as the laboratory of the bacteriologist. More than this may also be asserted. Every operating room ought to pursue careful and systematic experiments upon hand disinfection. No one believes that an ideal excellence has yet been attained. These fruitful experiments are alone possible in large operating rooms with frequent operations and abundant facilities for carrying on the work thoroughly. It is most gratifying to call to your attention the fact that two large operating rooms have lately been constructed in New York with every facility for this systematic work. If they contribute, as they undoubtedly will, to the simplification and perfection of surgical technique, their erection will fully justify the outlay, as large as it may seem to the unthinking critic.

(4) *Photographic Rooms.* — An equally important part of the educational outfit of a general hospital should be a well-constructed and well-arranged room for photography. Here medical men should be trained to do photographic work in the various departments of hospital service. Each man should be taught the manipulation of cameras and photographic plates, and should learn methods of developing, printing, enlarging, etc. Photo-micrography has proven a very disappointing branch of photography. A poor drawing which accurately portrays what the observer sees is generally much to be preferred to the most finely finished microphotograph with its blotches of color and flattened surface. Not so, however, with what may be termed

gross medical photography. Its field of usefulness is apparently limitless. Many surgical conditions should be photographed upon the spot, even while an operation is in progress. The rapidity and accuracy with which newly-discovered or newly-recognized forms of disease have been made known to the medical public, are well shown by the disease known as acromegaly. Although this disease was first differentiated and described by Marie, in 1886, its peculiar *facies* became at once familiar to physicians throughout the world by the excellent photographic reproductions which were distributed, and to-day it is easily recognized wherever found by medical men who have never been shown a case. In a similar manner cases of myxœdema and the various forms of paralysis have been accurately portrayed, to the great advantage of the student of medicine. Photographs of skin diseases, deformities, muscular atrophies and hypertrophies, ulcers, tumors, aneurisms, surgical operations, surgical methods and surgical dressings, perpetuate these conditions much more clearly and satisfactorily than pages of description. In many instances these representations are sufficient to enable the observer who has not seen the case to confirm the diagnosis.

(5) *Charts and Graphic Representations; Histories.* — Allied to photography are the various forms of charts and graphic representations. These should be made with absolute accuracy and regularity, and should form permanent records in the hospital. The same is true of medical histories, which ought to be made up daily at the bedside. Such medical histories should be classified, indexed, catalogued and rendered accessible so that any fact of medical interest may be referred to at a moment's notice. There should be a medical staff large enough to do this work thoroughly well. The influence of these careful records upon medical knowledge can hardly be estimated; their greater influence in training medical men connected with hospitals, to habits of careful, painstaking, exhaustive observation and faithful records of the same, is undeniable.

(6) *Dispensary Work.* — The position of carefully conducted medical work in dispensaries or departments for out-patients in training medical men is well recognized. The patients who present themselves for treatment at these clinics, more nearly represent the patients with whom physicians come into daily contact than ordinary hospital patients. Hence the same necessity in dispensary practice of training students in habits of quick, accurate and thorough diagnosis and of painstaking records of the clinical facts which are obtained. Clinical methods and clinical records ought to be as systematic and complete in the dispensary as in the hospital. The facilities afforded by a dispensary for the study of physical diagnosis are, if anything, more valuable than those of a hospital. The same is true of the opportunity for learning the methods of diagnosis in minor surgery and the application of the ordinary surgical dressings. Practical work in the diagnosis and treatment of diseases of women is here feasible, and under competent supervision often proves most valuable. The opportunities for studying the specialties of medical practice are also of extreme value and should be utilized regularly. Every department of a dispensary ought to be under competent expert medical supervision, and all branches should be so conducted as to promote the training of students. The practical difficulty in many dispensaries is that the clinical material is not properly utilized.

(7) *Libraries, Reading-Rooms, Societies and Journal Clubs.* — Every hospital should foster a good medical library and a reading-room filled with the best and latest medical periodicals, and all members of the staff should be expected to use them, and should have time to do so. In most hospitals the medical men are sadly overworked, and through a superabundance of routine work lose all time, and too often all inclination, for medical reading or study. The advantages of a medical society and of a journal club are too obvious to require more than a mere brief mention. These organizations should exist in the staff of every large hospital.

(8) *Medical Staff.* — A careful consideration of the subject leads me to urge that all large hospitals be furnished with an increased medical staff, and that the terms of service of a portion, at least, of the medical men be considerably increased. It is evident to all who have watched hospital work, that the usual term of service extending over a period of twelve, sixteen, or eighteen months, brings active young men fresh from medical schools into hospitals to send them out to give place to other inexperienced young men about the time they are fitted to do independent work. The hospital, consequently, suffers from the mistakes which they make while they are receiving training, and by an inexorable rule loses their services as soon as they are fairly well trained to do efficient and fruitful work. This difficulty would be removed if arrangements could be made to give all fourth-year medical students routine hospital duties under competent supervision. This would train them in practical work to such an extent that when they assumed hospital appointments they would be fitted to undertake independent work, and could supervise the work of other fourth-year men wisely. In each department of hospital service a chief resident should be appointed whose term of service should extend over a period of at least three years. This would enable him to fit himself thoroughly for giving instruction to all assistant resident physicians, and to wisely direct their work. Such service is possible in European hospitals, and if a similar service could be inaugurated in the leading hospitals of this country it would mark a decided advance in hospital work.

In conclusion, I would urge the duty upon every hospital of doing every branch of hospital work as well and as thoroughly as it can possibly be done. If philanthropy recognizes it to be a duty to care for the sick poor and to minister to their comfort by convenient, well-appointed, well-ventilated and well-warmed apartments, the same duty demands that their medical care shall be equally thorough, painstaking and scientific. The best should be constantly striven for; and nothing but the best should satisfy those who are charged with their care. Every hospital should be an object-lesson in the proper care of the sick. It should demonstrate the best methods of medicine, surgery and gynecology, the most approved nursing, the best cooking for invalids and their kindest care.

IN India, 21,389 persons were killed by snakes in 1891, as compared with 21,361 in 1890. It is said that in many places in India snakes are bred with the object of getting the government reward for all snakes killed. The abuse is so great that it is proposed to abolish the system of rewards.

Clinical Department.

ABSCESS IN THE CEREBELLUM.

BY T. A. KENEFICK, NEWPORT, R. I.

ON the evening of June 28, 1892, a tall, robust Englishman, aged twenty-three, called at my office and complained of a severe pain in the top and left side of his head. He gave no other symptoms. There was no specific history. His temperature and pulse were normal, tongue slightly furred, skin and eyeballs slightly jaundiced. Had been employed as assistant steward on board a yacht for the past two months, and during this time he has not felt exactly right, and attributed it to the life on ship-board. He has also grown deaf, and his mates say he seemed duller and less active, being threatened with dismissal for his stupidity.

Phenacetine, calomel and small doses of morphine were prescribed that night, but gave no relief; the next morning he appeared in the same condition.

Fearing typhoid, he was advised to enter the Newport Hospital, and was admitted during my service. The next day, June 30th, at 10 A. M., pulse 88; temperature 97°, the pain still persisting. At 4 P. M., the pain had left the top of the head and centred at the base of the brain, the pulse now being 80, and the temperature $100\frac{2}{5}°$. 8 P. M., temperature 101°, pain increasing; patient restless and wakeful, morphine one-eighth of a grain hypodermatically, gave two hours sleep, when he awoke vomiting greenish matter, and complained of increasing deafness.

July 1st, 8 A. M., temperature 99°, and remaining so until the evening, when it reached 101°; the pain again increased, causing the patient to moan constantly unless under the influence of morphine.

July 2d. There was no evident change in his condition; his pulse and temperature were the same; he retained his nourishment and bowels were regular and normal. At 2 P. M., he became delirious, and at 4 P. M., his temperature was 104°, and pulse 88, with marked tenderness in the right iliac region. Phenacetine, five grains, was given every two hours, and at 8 P. M., temperature registered 102°, and there had been some diarrhœa, light in color.

The course of the temperature, the presence of clay-colored stools, iliac tenderness and deafness suggested typhoid fever, but his general appearance was rather against it, and a diagnosis was withheld.

July 4th, at 12.30, he had his first and only chill, lasting three-quarters of an hour, followed by a profuse perspiration, but no rise in temperature. For the next few days he remained fairly clear, mentally, had an irregular pulse and temperature, and was kept comfortable by injections of morphine.

The morning of the 7th, he sat up in bed, his head bent forward on his chest, and complained of slight muscular rigidity. He could, with some assistance, resume the horizontal position, but only for a moment, as it gave him severe pain. The continued low temperature and the absence now of the right iliac tenderness and his fairly good mental condition did not confirm the first suspicions, and that idea was abandoned; but the presence of the fearful and persistent pain at the base of the brain, increasing deafness, retention of urine, some vertigo, and the peculiarly rigid condition of the muscles, all pointed to a serious lesion, and a definite diagnosis was made of a tumor at the base of the brain.

In this flexed condition, sitting up in bed, his arms encircling his knees and his head resting on his arms, he remained for thirty-one hours, taking a fair amount of nourishment, and growing more and more irritable and difficult to manage, until the morning of the 9th, when he suddenly stretched out on the bed, breathed with difficulty, and before the nurse could reach him he was dead.

An autopsy was obtained and performed in the presence of Drs. Beverley Robinson and Ecroyd. On dividing the scalp and calvarium, blood flowed very freely, which might be accounted for by the prolonged flexed condition of the body. Dividing the cerebellum at the base, there was found a cavity large enough to hold a billiard ball containing a quantity of greenish, horribly offensive pus, which was also scattered over the adjoining surface, probably occurring at the time of rupture, causing the sudden death.

It was evident that the process of suppuration must have been of long duration and of spontaneous origin, as the other organs were healthy. Special effort was made to find ulcerative patches along the intestine without any result.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

EIGHTH ANNUAL MEETING, AT WASHINGTON, D. C., MAY 30, 31 AND JUNE 1, 1893.

FIRST DAY. — MORNING SESSION.

PRESIDENT'S ADDRESS.

PRESIDENT LOOMIS, in his opening address, said in part: We have just celebrated, as nations count, our fourth birthday, yet the word American stands before the world for all that is most advanced in science. As we enter upon the new century year, it should be with the full appreciation that the theory and practice of medicine have given place to the science and art of medicine. The nature of this change cannot be more tersely or aptly described than in the words of Ruskin, "the work of science is to substitute facts for appearances and demonstrations for impressions," which plainly means that all our errors in science are subjective. The day of speculative medicine has passed; henceforth we must know, not suppose; and whatever is offered in public must have the stamp *scio*. The tripod support of science is *observation, theory, demonstration*. The first gathers facts, the second considers their relations, and the third tests all. Scientific scepticism is perhaps the most striking characteristic of medical investigation to-day — a scepticism which doubts, not for the sake of doubting, but which demands proofs and counter-proofs; which scans facts, not men, and learns to recognize truth from whatever source it may come. As a legitimate result of this spirit, there has been developed what is without question the greatest advance in methods ever made in medical science. When the medical history of the last half of the nineteenth century shall be written it will be largely that of the laboratory. Among the names which the twentieth century must honor none will stand higher than those who having devoted themselves to establishing objective facts of medicine were not beguiled by their

work to elevate the experimental above the practical. Let us, also, who are brought into such intimate relations with the practical, see to it that we are equally wise and self-controlled. The experimental alone can never accomplish the great work that is ever before the physician. It assays, indeed, the solution of ultimate problems, and seeks to grasp the primal forces of disease; but it must perforce grapple with each one singly, never with all those infinite combinations which make up the sum of what we call disease. We can never safely ignore the rich store of clinical facts gathered by so many master minds, or let them be withdrawn within the recesses of the laboratory. Although from the laboratory we hope to receive the solution of many problems which have long baffled us, it must be remembered that the special field of medical investigation is, and ever will be, disease in its activities — all its forces can be studied and understood only at the bedside of the patient.

Dr. Loomis, in closing, spoke of the death of two of the members during the past year — Dr. William Geddings and Dr. George Ross. Both these men did all that man can do. They did their part in life with faithful zeal until their powers gave way; and with the wisdom which never dwells in sordid minds they did not leave their mental wealth for legacies, but day by day transferred it to men with fresher strength, and gave over, not gave up, their work, content in the knowledge that it was not to cease, but grow larger year by year; and when, at last, their summons came, the best of all they had, the essence of the man, his quality, they left with us. Both were in the prime of their years, yet their fifty-five and forty-seven years are added to those marks of death from which the years are slowly crystallizing out the deepest spirit of our work. At present the world calmly reads those lines of silent figures, and carelessly says, "Yes, doctors are the shortest lived of all the professions," and thinks no more of what that means. Perhaps the world will never stop to think; but in that day when all our books are closed and other books are opened, who looks along the line until he finds "Physician," will look in vain for the small fraction of life's span, but may read instead, "he saved others, himself he did not try to save."

ON THE COURSE AND TREATMENT OF CERTAIN URÆMIC SYMPTOMS,

by Dr. Beverley Robinson, of New York.

Renal insufficiency *versus* uræmic symptoms. Adopt the former name to cover a definite series of symptoms. Cases reported which serve as a text to explain views upheld. Cases of inflammation in the respiratory tract, due to functional inactivity of the kidneys. Symptoms similar to those in the cases reported sometimes connected with organic renal changes. Treatment in the evident gouty cases with renal disease. Occasional inefficacy of the nitrites. So-called increased arterial tension merely the consequence of atheromatous thickening of vessels. Whenever renal function is insufficient, watch carefully the use of digitalis. Pernicious effects of even small doses of opium in chronic renal disease. Changes in the urine in interstitial nephritis. The hypodermic use of morphine in chronic Bright's disease; to be used with great care when the heart is weak primarily; not to be used even with weak heart when the pupils are contracted; in doubtful cases abstain from the use of morphine; in convulsive seizures of acute uræmia morphine frequently produces remarkable curative effects; in some instances, after the use of morphine, there are profound coma and contracted pupils, showing perhaps evil effects of morphine. Reflections as to the rôle of the kidney as an elective filter — the different poisons retained in, or eliminated from, the economy; various morbid effects produced by their retention. Primary source of uræmic symptoms not to be found either in the kidneys or heart, but often in the digestive tract. Intestinal antisepsis. Value of oxygen by inhalation.

Dr. James Tyson, of Philadelphia, supported the views of Dr. Robinson as to the effect of opium upon chronic kidney disease, and its tendency, in his experience, to invite coma and convulsions. He had seen two drachms of paregoric cause an old man to pass into coma from which he never recovered. Doubtless many cases of uræmic convulsions in puerperal eclampsia are successfully treated by hypodermic injections of morphia. It is in cases of chronic interstitial nephritis that morphine is dangerous. Cases of puerperal nephritis are cases of parenchymatous inflammation of the kidney and morphine is borne better in cases of parenchymatous inflammation than in cases of interstitial inflammation.

Dr. W. W. Johnston, of Washington, thought that the class of cases described by Dr. Robinson were very common, and more so than formerly. He had read a paper on this subject about eighteen months ago, in which were presented cases almost exactly analogous. His conclusions as to the nature of these cases were very much like those of Dr. Robinson, except that he gave greater prominence to the intestinal condition as the primary cause of the diseased state. There is but little doubt that the primary source of these disturbances is situated in the digestive tract, and it is the accumulation in the blood of the morbid products of digestion that starts the train of phenomena. In many of these cases the explosions are due to the inability of the kidney to excrete these excessive altered albuminoid products. Another cause may explain some of the acute attacks, namely, that they are the result of acute absorption of toxic matters from the intestinal fermentation. Some cases are too sudden in their onset to be due to renal inadequacy.

Dr. I. E. Atkinson, of Baltimore, spoke of the use of opium in uræmic conditions. There is no therapeutic fact, he thought, more capable of demonstration, than the extreme value of opium or the hypodermic use of morphia in the treatment of dangerous uræmic symptoms, especially in the sudden and acute œdema of the lungs that come on in the course of contracted kidney. When called to an early attack of œdema of the lungs in the course of contracted kidney, he felt that in five or ten minutes after administering morphine hypodermically, he would see that cyanosis disappear, the breathing become more quiet, and in the course of half an hour or so, the patient restored to his usual condition. It is a little strange that where one can relieve very promptly by the use of morphine a condition of extreme distress and danger, that the same therapeutic measure should be so dangerous in conditions of mild renal insufficiency; that morphia should be a dangerous remedy when the degree of toxæmia is mild, and a remedy of great value when the degree is extreme. Testimony shows that dangerous symptoms do sometimes succeed the administration of small doses of morphine; but the explanation may

be found in the fact that the symptoms are increasing at the time of the administration of the morphine, and would continue to increase no matter what was administered. The severe symptoms, in other words, follow the administration of the opiate but are not in consequence of it.

DR. ALFRED L. LOOMIS, of New York, said that when he brought the hypodermic use of morphia for the control of acute uræmia before the profession he had stated very positively that it was for acute uræmia and not for chronic, and for those cases of acute uræmia where there was no knowledge of any previous renal disease (such cases as are seen in acute parenchymatous nephritis, in the various infections, and which occur in connection with exposure to wet and cold). Those that came on during child-birth were particularly the cases which he had brought before the profession as being relieved or controlled by the plan of treatment. Afterwards he had found that morphia was being used in cases of chronic uræmia, which was an entirely different condition. If it is used indiscriminately in chronic uræmia, a great deal of harm may be done. Only in those cases of chronic uræmia where you have a large and dilated heart and where œdema of the lungs occurs, partially on account of the uræmia and partially on account of the condition of the heart, should opium be used; and in these cases opium is a power because it controls the heart.

DR. BEVERLEY ROBINSON, of New York, said that he was strongly convinced that the junior members of the profession had used opium in the treatment of uræmia so inconsiderately and so unwisely that in a great many instances much harm had been done. We know very little about the direct influence of structural changes in producing marked uræmia; and as Sir Andrew Clarke has pointed out, we must look, after all, in our interpretation of the disease, to the functional derangement rather than to the pathological changes.

(To be continued.)

Recent Literature.

A Medical Hand-book for the Use of Practitioners and Students. By R. S. AITCHISON, M.B., C.M., F.R.C.P.E. London: Charles Griffin & Co. Philadelphia: J. B. Lippincott Co. 1893.

This is a small hand-book of somewhat over three hundred pages, suitable to carry in the pocket, containing the pathology, diagnosis and treatment of all diseases, besides much other useful information. It might be useful to a physician to carry in his buggy to refresh his memory, or to the student to help cram for an examination. It contains, perhaps, as much as could be expected of a book which condenses to such an extent.

The Year-Book of Treatment. Philadelphia: Lea Brothers & Co. 1893.

This small volume gives a critical review, for practitioners, of the current literature of treatment in all departments of medicine and surgery. Many of the brief abstracts are valuable and suggestive, although being written by different men they vary widely in their value. A good deal of what is contained in such a book is of little importance, as it necessarily includes much that is evanescent in character.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 10, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

BACTERIAL POISONS.

No subject at the present day can be more interesting, and yet but little is known respecting bacterial poisons. The work of Gamaleia,[1] despite its literary merit and the great array of facts, is a little disappointing, and one really wonders on reading this book that so much could be written, and so little information given.

The first experiments of Seybert, Gaspard Stich, Magendie, Dupuis and others established the symptoms and lesions of experimental septicæmia. Panum showed that it is produced by a chemical poison: Bergmann and Schmiedeberg determine this poison to be an alkaloid sepsine. This result marks a first stage in the investigation. Down to about 1870 Panum's views were almost universally prevalent. Bergmann's sulphate of sepsine, obtained in crystalline form from putrid infusions, was believed to be the veritable putrid poison that causes septicæmia, and the action of microbes was ignored. Sepsine was thought to be a ferment, acting in infinitesimal quantity.

It was, however, soon found to be impossible to ascribe all the forms and symptoms of septic poisoning to sepsine alone, and that the poisons produced by putrefaction were many and various, according to certain conditions; and there was for many years a contest between the chemical and the vitalist doctrines, ending in the victory of the latter. Liebig's hypothesis that the soluble ferments are albuminoid matters in process of decomposition, was overthrown by Pasteur, who demonstrated that fermentation and decomposition do not exist apart from the life of organized ferments. Moreover, the contagionists were soon able to prove the fallacy of the chemical doctrine by showing that certain microbes separated from their morbid products were able to produce determinate diseases. At the same time was established the fundamental no-

[1] Bacterial Poisons, Detroit, 1893. (American Edition, translated by E. P. Hurd, M.D.)

tion, proclaimed by Cohn, of the specificity of bacteria, and bacteriology took its place among the sciences. The vitalist doctrine was not, however, in absolute contradiction to the chemical; and Panum has the merit of having understood the possibility of reconciling the two theories. He affirmed, that "it is incontestible that the putrid poison is chemical, but that it might be produced by a microbe, even a determined microbe. In diseases, both the pathogenic microbe and the production of the poison by the microbe, may play their respective parts." These words, uttered in the infancy of bacteriology, have been shown to contain a profound truth.

The discovery of ptomaïnes by Selmi, Brieger, Gautier and others marks the next stage in progress. These discoveries date from about 1870. The list of cadaveric alkaloids naturally resulting from putrefaction of albuminoids was soon quite large; and the query was soon raised whether it might not be dangerous to eat flesh, or even fish, and other animal products, for fear of ptomaïne poisoning. At least, invalids with weak digestive functions were warned of the danger. Later on, a careful criticism of the work of Gautier, Nencki, Brieger and others justified looking with suspicion on their different methods of extraction of ptomaïnes. There is even warrant for believing, as Gamaleia shows, that these methods were likely to create artificial products which did not pre-exist in the albuminoids analyzed.

A part of the work of these experimenters will still stand; but the spontaneous formation of ptomaïnes is not so constant a phenomenon as was taught, and the microbial poisons are not ptomaïnes. As for the typhotoxine of Brieger, Bassi has shown that it does not pre-exist in the cultures of the typhoid bacillus; and Salkowski has never been able to find the pepto-toxine of Brieger in the products of gastric digestion; in fact, Bouveret and Devic have proved this supposed ptomaïne to be "an artificial product which is formed at the expense of albuminoid matters by the combined action of HCl and alcohol."

Roux and Yersin, as a result of their experiments on the poison of diphtheria, conclude that by all its reactions the diphtheritic poison resembles diastases, and none the less by its intense activity in infinitesimal doses.

Gamaleia, after a somewhat exhaustive examination of the whole subject, and with the help of researches of his own, concludes, "that the toxic action of the bacteria is not linked to their fermentative action; it does not coincide with any known diastasic action." The microbial poisons have been supposed to be "secretions"; nevertheless, this comparison with secretions accounts but superficially for the facts. "First, there are certain pathogenic bacteria which produce such diseases as tuberculosis, cholera and charbon, where we do not find any toxic secretions. Then, again, even the production of poisons in diphtheria and tetanus has a very superficial correspondence to a secretion. In fact, the quantity of these poisons in the culture liquids does not grow proportionately to the development of the bacteria themselves. On the contrary, an attentive observation reveals the following facts: At the very first, and at the most active moment of the life of the microbes, the liquid of culture is acid, and devoid of all toxic power. Later, when the bacteria have ceased to multiply and are deposited at the bottom of the culture flask, the liquid becomes alkaline and very highly toxic. Its toxicity augments progressively with the duration of the sojourn of the bacteria in their alkaline liquid of culture."

The explanation of this fact he finds very simple: "The poison is contained inside the bodies of the bacteria, and is extracted slowly by the alkaline liquid in which they are macerated."

We have not time to pursue the subject further, and must refer those interested in the subject to the treatise itself. In short, Gamaleia believes that the microbian poisons "are the results of the creative syntheses of the bacteria, and come from their bodies.

"Thus is again confirmed our hypotheses respecting their chemical nature, which identifies them with the constituent parts of the nuclei of cells — the vitellines and nucleines.

"The toxicity of the microbian bodies may have also a teleological signification explicable from the point of view of the struggle for existence and of natural selection: for the toxicity of the bodies of bacteria may be useful to them as a means of preserving them against aggressors which would devour them."

THE ONLY ORIGINAL JACOBS.

AN enterprising firm issues a combination circular containing the following useful information for the medical profession: "Board and Rooms at the Columbian Exposition; Vaccine Virus; and Lithograph or Chromo for Embellishing a Physician's Office or Drug-store."

A remarkable statement in this circular is the following: "The source of the vaccine is '*America's only authenticated case of spontaneous cow-pox.*'"

There was a period, beginning about 1870, when the word "Beaugency" was employed very largely in the United States as a synonym of purity and unusual value in connection with the production and sale of vaccine lymph. The commercial value of this term to the vaccine purveyor, was undoubtedly considerable. If, however, the researches and the rapid progress of the past few years in the study of the natural history of infectious diseases have proven anything, they have shown quite conclusively that the *spontaneous* or *de novo* theory of the origin of infectious diseases is a shadowy myth, and that such diseases have their origin in previous cases, with as much certainty as the fact that the oak tree always springs from an acorn, or the field of grain from a previous sowing of the same kind of grain. If we cannot discover the

source of an infectious disease, or trace its origin, we have no right, therefore, to assert that such source or origin does not exist.

Infectious diseases are the common property of man and the lower animals; and in asserting to himself a sort of proprietary right in any particular case of infectious disease, man is transgressing the pale of nature's laws, since such infections are a common property and a common liability of all.

Moreover, cow-pox is not so rare an occurrence in the United States as the circular in question would lead us to infer. In Wood's "Reference Hand-book" (article *Vaccination*), at least twenty well-authenticated cases of cow-pox in the cow are mentioned as having been examined and reported by several different observers in the United States, mostly between 1870 and 1880. These cases occurred mainly in years and in districts when and where small-pox was prevailing, and only corroborate the evidence accumulated in earlier times by Ceely of England, and recently by Haccius and Eternod of Geneva, Dr. Simpson of Calcutta, and Dr. King of Madras, that cow-pox is simply a modified small-pox.

There has always been an attempt on the part of the commercial vaccine purveyor to show that cow-pox is an extremely rare disease, and that Messrs. So-and-So are the only possessors of and dealers in the original and genuine authenticated spontaneous article. It is not creditable to a great and liberal profession to lend its aid to so-called theories of the source of infectious disease which have their origin in commercial methods and not in the careful investigations of science.

In those countries where the general government furnishes the supply of vaccine lymph, as in Germany, Belgium and Italy, the term *spontaneous cow-pox* is rarely used. Cases of cow-pox occasionally occur; and when they are observed, they are not unfrequently resorted to for the purpose of renewing the stock of lymph, as in the recent cases in Wiltshire, England, and Eysines and Cérons in France.

In Germany there are at present twenty-five cities, in each of which is a well-equipped vaccine station for the purpose of supplying vaccine lymph from the heifer. The demand for lymph is not, as in America, largely due to the spasmodic efforts of local boards of health exerted in time of small-pox epidemics, but is the result of the continuous and uniform execution of the law of the country, requiring the vaccination of all infants and the re-vaccination of all who have arrived at the age of twelve years. As a result of the enforcement of this law, Germany is to-day, and has been for the past fifteen years, more free from small-pox than any other country in the world.

Thus far in the United States, only one or two States have made provision for the furnishing of vaccine lymph by the government. In Minnesota the State Board of Health conducts such an establishment, and furnishes lymph to physicians throughout the State.

POSTPONEMENT OF THE INTERNATIONAL MEDICAL CONGRESS.

WE have just received the following letter:

NEW YORK, August 6, 1893.

MR. EDITOR: — The undersigned, chairman of the American National Committee of the Eleventh International Congress, has received the following cablegram:

GENOA, August 4, 1893.

DR. JACOBI, 110 W. 34th St., New York. Congress postponed to April, 1894. Letter follows. MARAGLIANO.

This official information, communicated by the secretary-general of the Congress, interrupts the preparations made for it. As many of our medical fellow-countrymen have been preparing to visit the Congress, which was to be held on September 24th, I trust you will give the news herein transmitted the greatest possible publicity.

Very respectfully, A. JACOBI.

It will be remembered that there was a rumor during the spring that the International Congress would be postponed on account of the question of sanitary safety, which, of course, meant the danger of cholera. Cholera has existed in Naples during the past month, and has this week been reported by cable to have appeared in Rome.

The Congress was to have met on the 24th of September, and it is probable that this postponement is due to the possibility of a serious outbreak. It will be a disappointment to those who have already made preparations for attending the meeting this autumn; but, on the other hand, the month of April in Rome is delightful, and it is possible that as many may be tempted to go at that time. The change in time will also, perhaps, increase the attendance at the Pan-American Congress in Washington, and also the number of physicians, both American and foreign, who will visit the World's Fair in Chicago.

MEDICAL NOTES.

THE CHOLERA. — The cholera in the East has on the whole decreased during the last week. In Turkey and Russia there have been cases reported from several new districts, showing a moderate general spread of the disease. In France, and especially in Marseilles, the death-rate has increased; there being now a daily mortality in Marseilles of nearly twenty-five. During the last four weeks there have been 826 deaths from cholera throughout France. In Italy the government has still remained careless to the increasing number of cases, and the official reports from Naples are much understated. There are at present about fifty new cases and thirty deaths daily. There has been a veritable panic among the residents of the city, and many thousands have fled. Several sporadic cases have occurred in Rome. In the interior districts of the Mediterranean shore there has been no marked increase.

THE CHAMBERS STREET HOSPITAL, NEW YORK. — A correspondent of the *Medical Record* writes concerning the erection of the new building for the Cham-

bers Street Hospital, that, spacious and modern as the new rooms may be, the older ex-house-officers will remember with pleasure the small, inadequate buildings in which the great work of the institution was carried on. A cause for especial pride is the record of work between the years 1876 and 1888, when the hospital staff, under the lead of Dr. William T. Bull, so carefully studied and thoroughly carried out the details of antisepsis in its early days, that the hospital may claim to have contributed not a little to modern surgery.

The Diphtheria Outbreak in New Jersey. — Dr. Hunt, medical inspector of the New Jersey State Board of Health, has reported upon the outbreak of diphtheria occurring at Hightstown in that State. He found that eighteen of the twenty cases investigated were in families supplied by the same milk-man, in whose employ was a lad suffering from diphtheria, but at work in the dairy. The general sanitary condition of the town was good, and had no part in the epidemic.

Admiral Tryon's Illness. — So much has been said about the illness from which Admiral Tryon was recovering at the time of the loss of the *Victoria*, and its effect upon his nautical judgment, that it is interesting to read the testimony of the fleet-surgeon before the court-martial. The admiral had an ulcer upon one leg which was exceedingly slow in its healing, necessitating over a month's absence from duty. There was no fever or general disturbance beyond the local trouble.

Ante-mortem Burial.—Seymour, the mind-reader, who a short time ago announced his intention of being buried alive to test his power of suspending animation is having great difficulty in carrying out his plan. He intended to be buried in an especially constructed casket which communicated by an electric wire with the surface. Over the grave some corn was to be planted and when this had grown and ripened Seymour was to be dug up. His difficulty has been to find a grave. No cemetery company will allow his interment in its grounds, and Seymour has so far found no one who will take the responsibility of burying him anywhere. It looks as if this fool-hardy experiment would be made impossible, as it is to be hoped it will.

Fifteen Pairs of Twins. — A correspondent of the *Lancet* reports a bit of domestic history which is wonderful, if true. A woman in making a contract statement for life insurance solemnly asserted that her father died at the age of eighty; that her mother was alive at the age of seventy-nine; that she had four brothers and four sisters alive and in good health; that her mother had "had thirty-three children, fifteen times twins," and that "twenty-four died under six months old." The writer while he would not vouch for these facts saw no reason to discredit the woman's word or honesty.

Cure of a Case of Movable Liver. — Richelot reports to the Académie de Médicine the successful cure of a case of movable liver. The patient was a woman, twenty-eight years old, who had suffered for some time with abdominal pain. The right iliac fossa contained a large, firm tumor which on operation proved to be the liver, which had fallen downward into a vertical position and had become adherent in places to the cæcum. The bands were broken up, and the liver replaced and fixed by three sutures passing through the thickness of the abdominal parietes and Glisson's capsule. The recovery was uninterrupted, and the displacement had not returned.

A Reception in honor of Prof. Adam Politzer, of Vienna, was given at the University Club in Boston last Tuesday evening by Drs. C. J. Blake, J. O. Greene and H. L. Morse.

New York.

Contaminated Wells in Central Park. — Dr. T. F. Janeway having reported that he had attended three patients suffering from intestinal trouble which was produced by drinking the water of a well situated near the tennis courts in Central Park, the Board of Health requested its chemist, Dr. Martin, to make an analysis of the water, and the result showed that it was contaminated with sewage. In consequence, the well was condemned, and ordered to be closed, and Dr. Roberts, Sanitary Superintendent, has requested the Park Commissioners to furnish him with a list of all the wells and springs in the Parks in order that their waters may be submitted to analysis.

A Dinner to Dr. Politzer. — Dr. Adam Politzer, the celebrated otologist, who is an official delegate to the Columbian Exhibition at Chicago from the University of Vienna, arrived August 3d on the *Aller*, and on the evening of the following day he was given a dinner at the Union League Club by Dr. Gorham Bacon, which was attended by a considerable number of well-known New York physicians.

High Mortality. — The climax of the summer's mortality was probably reached during the week ending July 22d, when the number of deaths reported was 1,257. In the following week the number was reduced to 1,084; representing an annual death-rate of 29.83 per thousand of the estimated population, which is about the same as that of the average of the corresponding week for the past five years. During the corresponding week last year, when the weather was intensely hot, the number of deaths reached 1,434; representing an annual death-rate of 40.83, which is about the highest in the history of the Health Department.

Miscellany.

MR. HART'S IMPRESSIONS OF THE MEDICAL PROFESSION OF AMERICA.

Mr. Ernest Hart, on his return voyage, wrote for the *British Medical Journal* a preliminary report of his visit to this country. His visit was a most pleasant one in every way; and the cordial greetings he received from the various professional bodies left upon

his mind, he says, a succession of vivid pictures of the self-respecting originality, the marked regional individuality, the friendly but distinctive competition for progress and leadership of North, South, East and West.

Two of the pictures are of especial interest: "New York, with its wealth of clinical material, its largely developed hospitals and schools, and its prosperous practitioners and consultants, has a certain leadership which some think too self-confident, with its roots not yet deeply set. Boston cultivates with proud reserve and academic polish traditional thoroughness and a high university culture."

He criticises in a friendly spirit the causes of the imperfect professional union of different sections of the country, as being of importance not only to this country but to the medical profession at large. He looks upon the present time as a critical period in the development of professional life in America, owing to a tendency to sectional caucussing and special "congresses," which is threatening to limit the usefulness of much scientific activity. It deprives the "physicians," the "surgeons," the "laryngologists," and so forth, of the power for good which comes from mutual and common intercourse, and the cultivation of a sense of unity and affection, amiable criticism and common effort. "So much sectional difference has been aroused," he says, "and the organization of the annual sectional congresses all over the States has been so assiduously developed, that some difficulty may be found in restoring unity of sentiment and action. Nowhere, however, could the results be more valuable than in America of a common understanding on the relations if the profession to the public, and of their duties to each other. Nowhere does there exist a stronger need or a more useful sphere for medical thought and knowledge in guiding municipalities and executive officers in questions of public health and the government of public institutions, the endowment of science and the maintenance of adequate standards of education and examination. The future of the higher life in America and the development of culture and mental progress, the struggle against commercialism, and the blinding and corrupting worship of the dollar, lies largely with the professional classes. The medical tradition is essentially a protest and an antidote against this curse of new communities. The most superficial observer from without must see that this great attribute of medicine and this high duty and privilege are recognized and brought into play in very different degrees in the various centres of the United States. The newest settlements and States are far from being the least developed in this respect."

It was not only medical life which interested him and the great question of municipal sanitation which he so understandingly discussed in his addresses on the water-supply of Chicago; but the energies, capabilities and resources of our country were a source of great and deepening wonder, as he saw on all sides that which must make all Englishmen proud and happy — "unexampled vigor, unlimited resource, matchless natural marvels, a race of lovely girls, rapidly developing scientific institutions, and a growing passion for research, a continent in which lies the future of the world peopled by an Anglo-Saxon race."

It is his hope on his visit next fall to find a way of being useful in the direction of helping to a federation of the great medical forces of different sections of our country from the union of which in "a mutual and generous intercommunication, may be expected a hitherto unexampled development of professional usefulness and vigor in inspiring social action, in modifying further administration of health matters, in raising and purifying the standards of life, as well as in the advance of the art of healing."

ÆTIOLOGY OF PLEURITIS.

JAKOWSKI,[1] after bacteriological study of fifty-two cases of pleuritis, concludes that every pleuritis is of bacteriological origin, although the bacteria may not be found in the exudation. When repeated examination of a serous or purulent exudation shows no bacteria, the case may be considered as tubercular.

The majority of primary, non-tubercular pleurisies are due to the diplococcus of Fränkel. The next most frequent cause is the streptococcus pyogenes. Serous effusions containing these latter are much more likely to become purulent than those which contain only the diplococcus. The most favorable prognosis is to be given in cases which contain only the Fränkel diplococcus.

GASTRO-INTESTINAL EXHAUSTION.

AMONG the many cases of gastro-intestinal disturbances which occur in warm weather, a certain number may be fairly considered as a class by themselves, due not to poisoning or errors in diet, but best described as cases of gastro-intestinal prostration. The clinical picture is fairly definite. The onset is slow, as a rule; indeed the patient is often unable to give a more accurate date of the beginning of his trouble than "the first of warm weather." There is no history of errors in diet or exposure to cold — as there is no sudden onset of acute symptoms. A general mild anorexia for a day or two, slight irregularity in the action of the bowels and a little distress after taking of food, have hardly attracted any attention; but the continuance and gradual increase of a mild diarrhœal tendency are the first symptoms heeded. The diarrhœa is unaccompanied by pain, though often attended with flatus. Diet when at all rational has but slight connection with the diarrhœa.

The whole picture of the case when carefully noted is quite distinct from that of acute or subacute gastritis due to irritant ingesta. There is no fever or vomiting, though there may be slight nausea. The chief complaints of the patient are of the annoyance of the diarrhœa and of a sense of weakness. The ordinary treatment of a gastro-intestinal catarrh is usually given with a gradual improvement of the patient towards fall.

The noticeably good effect of a few cool days on the patient points to the rational explanation of the condition, the greater or less exhaustion of the nervous centres controlling the alimentary tract. The effect of heat upon the human system varies so much in different persons that it is not easy to trace the exact course of its workings. Some people are always "better" in summer, they like hot days, and with such people cases of gastro-intestinal exhaustion are not found.

[1] Zeitschr. f. Klin. Med., xxii, i, 2.

It is the person whose nervous system is below par, or easily exhausted by heat, who is troubled by this atony of all alimentary processes. Indeed, the digestion suffers only as a result of marked nervous exhaustion affecting chiefly the great ganglionic centres of the sympathetic system. With this theory of the cause of the patient's trouble the indications for treatment are seen to be quite different from those of an enteritis. The diet should, of course, be light and simple, but it should be abundant. The patient should be kept quiet, fed often and regularly, with varied but easily digested foods. Removal from a heated noisy city to cool localities is of the greatest importance, and care should be taken to avoid overheating or exposure to the sun. The nervous system should be given all the rest possible, as in cases of general nervous exhaustion.

Medicinal treatment should be not by cathartics and antiseptics for supposed ptomaïnes, but by thorough administration of nervous tonics and stimulants.

THERAPEUTIC NOTE.

QUININE IN CHOREA. — Dorland and Potts[1] report seventeen cases of chorea successfully treated with quinine. Hitherto the treatment of chorea has been by drugs which control the action of the motor nerves, or act as strong spinal depressants — in other words, blocking the manifestation of the disease rather than removing its cause. If chorea is due, as seems probable, to a greater or less diminution of the inhibitory power of a higher nervous centre, then the rational treatment is by drugs which stimulate and restore the function of that centre. Quinine appears to have this power to a marked degree and the results of seventeen cases treated with large doses are very promising. The children were from seven to fourteen years of age and were given four grains of quinine, four, five or six times a day until cinchonism occurred. The dose was then somewhat lessened and continued t. i. d. In most of the cases an immediate improvement took place and continued for some time. If the drug was used alone a relapse usually followed, but when combined with active treatment toward building up the general health gave permanent results. The large doses which most of the children took without cinchonism were remarkable.

Correspondence.

A POSSIBLE CAUSE FOR THE PRESENT PREVALENCE OF APPENDICITIS.

NEWTON LOWER FALLS, August 1, 1893.

MR. EDITOR: — "The smallest worm will turn if trod upon"; and the frequency with which cases of appendicitis are reported leads one to ask what new, broad-footed cause is trampling over the appendices vermiformes of the community. People are beginning to inquire in regard to this portion of the organism of which they now hear for the first time. Many explode in righteous wrath on learning that they possess an appendage, utterly useless in itself, but likely at any moment to become as dangerous a companion as would a stick of dynamite in their pockets. They regard appendicitis with much the same dread that they have for cholera, and wish to be told how to avoid it.

[1] University Medical Magazine, August, 1893.

Is the disease more prevalent than hitherto? Admitting that improved diagnosis and, not infrequently, actual inspection demonstrate to-day its existence in cases that a few years ago might have recovered or been buried under some other designation, it still seems that its apparently more frequent occurrence of late cannot be entirely accounted for upon that supposition. If this be so, it is time to ask in what manner the general condition of the community is changed — what especial causes are now operating to render persons liable to this disease, that were not in operation a few years since.

Food which we were formerly taught to regard as the usual cause of appendicitis, has not materially changed in its general character from what it was thirty years ago, and may be excluded. Not only are there no more berries eaten now than then, but a large number of the cases reported of late specify that no foreign body existed in the appendix. Clothing — while in its various fashions it may not only compress the abdominal regions, but may fail to properly protect them against harmful changes of temperature — is certainly at the present time no worse in these particulars than at any previous time during the past twenty years.

Looking beyond these two for a possible causal condition, however, we find in one particular a condition of recent origin which may possibly explain in some degree the frequency of the disease. I refer to the comparatively recent and very general introduction of methods of physical culture and the resultant growth of athletic sports. Calisthenics, as generally taught, appear harmless enough; but many of the postures involved cause a good deal of abdominal pressure. It goes without saying that where an overloaded ascending colon is subjected to such pressure, a portion of the fluid matter entering from the ileum might be forced downward into the appendix and be the cause of serious disturbance.

The danger from such a contingency would naturally be increased in the more violent gymnastics and the rougher athletic games — as base-ball or foot-ball, rowing, polo and the like. The position of the modern bicyclist when riding, seems very favorable to an injury of that description.

In short, any and all of these exercises are attended with a certain risk if taken when the intestines are overfull; and I am not aware that this fact has been given much prominence in published instructions and rules upon the subject. It therefore seems proper to call attention, both professional and lay, to the matter.

C. F. CREHORE, M.D.

A POSSIBLE OPPORTUNITY FOR WALTHAM WOMEN TEMPORARILY OUT OF WORK.

WALTHAM, MASS., August 1, 1893.

MR. EDITOR: — Among the hundreds recently thrown out of employment by the partial shut-down of the American Waltham Watch Company, are many young women of refined character, who would now be thankful for situations in families such as usually can be filled only at high wages or by those whose early advantages have been far less.

These young women are not experienced housekeepers, nurses or seamstresses; but they are ready to do their best in any such work and for moderate wages.

It occurs to me that in the practice of many of your readers there are probably families where the extra help thus available, would be welcome. And with the purpose of helping my townswomen in their present stress to such opportunities of earning their living, I offer my services as their agent. If parties desiring extra service will correspond with me by mail or wire, I will do my best to supply them. But, to prevent my falling into a permanent intelligence-office business, I beg to stipulate that my offer holds good only for this month of August.

Yours respectfully,

A. WORCESTER, M.D.

METEOROLOGICAL RECORD,

Deaths reported 4,437: under five years of age 2,606; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 1,906, consumption 343, acute lung diseases 214, diarrhœal diseases 1,602, diphtheria and croup 114, typhoid fever 50, whooping-cough 38, cerebro-spinal meningitis 34, scarlet fever 24, measles 20, malarial fever 6, erysipelas 5, small-pox 3, typhus fever 1.

From whooping-cough New York 14, Philadelphia 7, Pittsburgh 4, Chicago and Brooklyn 3 each, Cleveland 2, Boston, Washington, Nashville, Cambridge and Brockton 1 each. From cerebro-spinal meningitis New York 14, Chicago 6, Cleveland 4, Gloucester 3, Brooklyn and Marlborough 2 each, Philadelphia, Washington and Everett 1 each. From scarlet fever New York and Boston 4 each, Philadelphia, Brooklyn and Pittsburgh 3 each, Springfield 2, Chicago, Cleveland, Milwaukee, Cambridge and Everett 1 each. From measles New York 9, Philadelphia 4, Springfield 2, Chicago, Washington, Cleveland, Pittsburgh and Salem 1 each. From malarial fever New York and Brooklyn 2 each, Philadelphia and Fall River 1 each. From erysipelas New York and Brooklyn 2 each, Pittsburgh 1. From small-pox New York 2, Philadelphia 1. From typhoid fever New York 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending July 22d, the death-rate was 25.1. Deaths reported 4,866; acute diseases of the respiratory organs (London) 200, diarrhœa 1,126, measles 129, diphtheria 88, whooping-cough 83, scarlet fever 64, fever 44, small-pox (London 10, West Ham 5, Oldham 3, Bradford 2) 20.

The death-rates ranged from 12 7 in Bristol to 41.6 in Preston; Birmingham 24.6, Bradford 21.4, Croydon 20.6, Leeds 26.2, Leicester 31.3, Liverpool 34.9, London 22.5, Manchester 32.6, Newcastle-on-Tyne 23.0, Nottingham 27.4, Portsmouth 23.4, Sheffield 29.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 29, 1893, TO AUGUST 4, 1893.

MAJOR ALFRED A. WOODHULL, surgeon, U. S. Army, is granted leave of absence for one month and fifteen days, on account of sickness, to take effect on or about August 15, 1893.

Leave of absence for two months, to take effect about August 10, 1893, is granted CAPTAIN EDWARD C. CARTER, assistant surgeon, U. S. Army.

CAPTAIN WALTER D. MCCAW, assistant surgeon, is relieved from duty at Camp Pilot Butte, Wyoming, and ordered to the Presidio of San Francisco, California, for duty.

CAPTAIN RICHARD W. JOHNSON, assistant surgeon, will report on or before August 6, 1893, to the commanding officer Fort McHenry, Md., for temporary duty at that post during the absence of CAPTAIN CHARLES B. EWING, assistant surgeon.

PAN-AMERICAN MEDICAL CONGRESS.

SECTION ON PATHOLOGY.

Meeting: Washington, Sept. 5, 6, 7 and 8, A. D. 1893.

One session will be devoted to a formal discussion on the subject of Cancer, to be opened by Dr. Wernicke, of Buenos Ayres, and as co-referee, Prof. Allen J. Smith, of Galveston.

Another session will be devoted to Yellow Fever, the discussion to be opened by Drs. Acosta and Grande, of Havana, Cuba, and as co-referee, Dr. A. J. Amadeo, of Puerto Rico, Honorary President.

One day, two sessions, will be devoted to Practical Demonstrations.

JOHN GUITERAS, M.D., Philadelphia, Pa., *Executive Pres.*
DAVID INGLIS, M.D., Detroit, Mich., *English-speaking Secy.*
L. F. CRIADO, Brooklyn, N. Y., *Spanish-speaking Secy.*

SOCIETY NOTICE.

AMERICAN DERMATOLOGICAL ASSOCIATION. — The seventh annual meeting will be held at the Hotel Pfister, Milwaukee, Wis., September 5, 6 and 7, 1893.

GEORGE T. JACKSON, M.D., New York, *Secy.* and *Treas.*

RECENT DEATHS.

RICHARD H. SALTER, M.D., M.M.S.S., died at the Massachusetts General Hospital, August 4, 1893, aged eighty-six years. He graduated in 1831 from the medical department of Yale University. He was surgeon of the First Regiment of Massachusetts Volunteers, and did much toward raising and equipping the regiment at the outbreak of the Rebellion.

H. C. COOPER, M.D., died at Woodbridge, N. J., recently, aged sixty-four years. He was a nephew of Peter Cooper, and a graduate of the College of Physicians and Surgeons, N. Y. He served in the Rebellion, and was a prisoner for a time in Libby Prison.

ROBERT FOSTER DILL, M.D., Professor of Midwifery in Queen's College, Belfast, died July 20th, aged eighty-one years.

BOOKS AND PAMPHLETS RECEIVED.

The Outlook for Medicine. By Bayard Holmes, B.S., M.D., Chicago.

Lectures.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XIII.

DISLOCATIONS.

You recognize a fracture by crepitus and mobility, and by the fact that it will not stay in place after we have drawn it back into position; and, in gross terms, we recognize a dislocation by the fact that there is no crepitus, that it is stiff rather than movable, and that it does stay in place, if it is replaced into its proper position.

When a bone is thrown out of its position by some external violence, it makes no matter what, sometimes by a direct blow, or by a fall, or by a severe strain of the muscles, there are two obstacles which prevent its reduction. One is the painful and rigid contraction of the muscles, which pull upon the bone in its new position, and prevent it from going back; and the other is the ruptured fibres of the capsule and ligaments around the joint. This last impediment must vary a good deal. For instance, in a strictly encapsulated joint like the shoulder, and extremely movable joint, the bone slips out and goes through a rent in the capsule and rests in some new location. On the other hand, when the head of the thigh-bone happens to be thrown out of the acetabulum, it has two powerful tendons, so to call them, which resist reduction. One is the so-called ileo-femoral ligament, or Y ligament, described by Dr. Bigelow, which gets wound around the bone in various directions; and the other is the tendinous portion of the obturator internus muscles, which is more nearly a tendon than a muscle. These two forces prevent the bone from slipping back into place. Now in old times all these obstacles had to be overcome by direct violence; and hence the use of traction and the pullies. In a moderate case, the patient was held strongly, and the surgeon and assistants having put on what was called a clove-hitch on the arm or leg, pulled and pulled until the muscles were tired out, and the ligaments, which were in the way, were ruptured. The fibrous tissue was ruptured, and the bone finally was got back into its place. The more they pulled the harder the muscles resisted. Agony, of course, was inflicted on the patient. The spasmodic contraction grew harder and harder; and it was sometimes a matter of a half-hour to an hour, and sometimes several hours, before the patient's nervous force was finally exhausted, the muscles worn out and the bone got back into place.

The introduction of anæsthetics, besides producing profound sleep and unconsciousness to pain, is also found to relax the muscles just as they are relaxed in death; hence the giving of ether or chloroform to a patient, after they are profoundly narcotized, obviates entirely the muscular resistance, and that great obstacle is out of the way. There still remain the torn capsule, ligaments, fibrous bands, to strongly resist reduction; and these were, until quite recently, overcome by force; and the patient having been etherized, then traction was used. Sometimes even the pullies were employed with ether to force the fibres apart, and to let the bone spring back into the socket. Latterly, however, it has been found that this resistance also can be overcome without violence, by manipulation, bending, untwisting the opposing fibres, and thereby letting the bone slip back into the socket.

The reduction of dislocations now turns upon two points, — profound anæsthesia, and what is called manipulation, that is, tipping the bone about so that it will glide back into place, and get out of the folds of fibrous tissue which are embracing it. That marks the great distinction between the treatment of dislocation nowadays, and that in former times.

On account of difficulties of diagnosis it not infrequently happens that dislocations are not discovered; and the patient, at first thought to have a blow and sprain, is afterwards found to have a bone out of the socket, weeks or sometimes months, after the injury has been inflicted.

What happens if the bone remains always unreduced? Nature then alters, in the first place, the socket. It is no longer of any use; and it is filled up and changed by the deposits of new plastic material and bone, and becomes smoothed off, in time. Meanwhile the bone rests out of the socket, in some false position, upon another bone, or among the muscles. There nature gradually hollows out a new socket. A rim of bony tissue is built up around the head. A species of false synovial membrane is formed; and what is called a new, or false joint is made, to accommodate the movements of the part. It, of course, is never so good as the original joint; but it is, in many cases, a very fair substitute for it. This is especially true of the shoulder. Now the articulation of the humerus with the scapula can hardly be called a ball-and-socket joint. The head of the humerus plays almost upon a plane surface. There is no socket; and when this bone is thrown out and lodges in a new position under the coracoid, or in the axilla, the head rests in the soft parts, a species of synovial sac is formed, and a very fair subsequent use of the arm is had. On the other hand, when the femur is thrown out, nature forms gradually a new socket and places a bony rim around it, so that with great shortening and great inversion, the patient still has considerable power of moving the limb. Seeing that nature does this, it is a question whether we should attempt the reduction of dislocations after a considerable time has elapsed from the first injury. This question turns upon several points. We know, in the first place, that if we do not touch them, nature will patch up the injury to a certain degree, and that the patient will get a more or less useful limb. The question of attempting to reduce an old dislocation turns then upon two important points. One is whether, if we succeed, we can give a much better limb than nature would make if it were left alone; and the other is, what additional risk we shall put the patient and his limb in, if we attempt a forced reduction after a considerable length of time.

No exact rule, I think, can be laid down for the proper conduct of the surgeon in such cases. It must depend upon the joint; upon the individual patient; upon his age; upon his idiosyncrasies; and, the chief factor of all, upon the length of time that has elapsed since the injury was first received. It is obviously easier to make an attempt to break up adhesions if the humerus is thrown out of the socket, than it is in the case of the thigh; consequently, successful attempts

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

at reduction after old dislocations of the shoulder-joint are much more numerous than after dislocations of the hip. Unless the femur can be put back pretty soon after the injury is received, it becomes almost impossible to do it; and the question arises then, whether the division of the muscles and fascia, or section of the neck of the bone, may not be preferable to attempting reduction of the head of the femur to its natural place, by force.

What are the risks that we run in trying to reduce, at a late day after the injury? In old persons, breaking the bone. That is very common. Breaking the humerus, or the neck of the thigh-bone, if we attempt to reduce them. Then we have converted a dislocation into a fracture of the neck; which perhaps would not unite if we tried to make it; which we should better leave, and let it become a new false joint, just as it does in fracture of the neck in very old people, of itself.

More important than this is the injury, especially in the upper extremity, which is liable to be inflicted on the vessels and nerves which are pressing against the head of the bone when thrown out of the socket. Of course, in the normal state the large veins, nerves, artery pass down a little out of the way of the bone; but let that be thrown out, and vessels and nerves are compressed. Neuralgic pain is the consequence, and great swelling of the arm. If the bone remains in this position, nature accommodates herself to it, and the pain gradually goes away and the swelling subsides; but if, in the case of an old dislocation, we etherize the patient, seize the arm, and attempt to get it back into place, it can only be done by first circumducting it in various directions with a good deal of force, and then trying to pry it up into the socket. By so doing we run great risk of injuring the veins and nerves, and producing a neuritis, if nothing more; of not very infrequently rupturing the large axillary vein; and occasionally plugging, if not tearing, the artery. It is quite common, in attempting to reduce an old dislocation of the shoulder, to have the pulse lost at the wrist, and to have great swelling of the part below for some days after the reduction has been successfully accomplished; and if it is not easily and successfully accomplished, and if a long period of circumduction and breaking up has to be gone through before the attempt is desisted from, occasionally the vessels are so far injured that they fail to recover; the limb mortifies; amputation at the shoulder-joint is the only resort to save the patient's life; and the result is much more disastrous than if he were left alone. I do not mean to say that we should not attempt to reduce any old dislocation. We should take these things into careful account; the number of weeks it has been out; the age of the individual; how much nature will accomplish in such a joint if left alone; and the chances of injuring vital parts if reduction is attempted. The humerus has been put into place, many times, after sixty and seventy days; after eighty or ninety days it usually fails; and in old people the attempt has frequently sacrificed the arm. The femur, as a rule, will not stand attempts after so long a period; and unless dislocation of the femur is reduced within the first month or six weeks, I do not think there is very much prospect of getting it back into position. Of course, there are exceptional cases, where you read of brilliant success at an unexpectedly late period; but bear in mind that all these exceptional cases merely illustrate, and prove by their rarity, the more common rule, that the bone cannot be got back easily and safely after a certain length of time.

So to review, very briefly, we have these important points which govern every dislocation: We now can overcome muscular resistance by ether, and overcome ligamentous resistance by manipulation. We may attempt reduction of old dislocations. If we fail, we may still console ourselves with the belief, that a tolerable joint will be got by the efforts of nature, with the bone in its new position.

Dislocation of the Lower Jaw. — The first dislocation we shall speak of is of the lower jaw. Partial dislocation of the lower jaw forward at the eminentia articularis is a very common occurrence, and the bone snaps back itself. This is the case with many young subjects, especially females, where partial dislocation of one side takes place with a creaking noise, during gaping, or opening the mouth wide. The patient rubs the jaw a little, and the bone snaps back into place. Under profound anæsthesia we can, with the thumbs behind the angle of the jaw, partially dislocate the bone forward upon the eminentia articularis, and throw forward with it the glottis, and prevent the swallowing of the tongue.

Complete dislocation of the jaw forward over the eminentia articularis, up into the temporal fossa, puts the mouth into a peculiar and characteristic position — wide open, and the chin thrown out a considerable distance beyond the upper jaw. Dislocation of this kind on one side, of course, makes a peculiar deformity. The common thing is to have both thrown out.

Reduction is easy. The chief thing to guard against is the mutilation of the surgeon's fingers in making the reduction. It can be reduced by putting both thumbs inside of the jaw, pressing the ramus down and back, and it will slip up into place. It is thrown out over the eminentia articularis, and you push it down and it will glide back into place. Previous to doing this some firm substance should be put into the mouth so that the jaw cannot shut on the thumb of the surgeon while making this manipulation; or the fingers can be guarded with something to prevent cutting by the teeth. Perhaps it is not worth while to delay longer on this. It is not common. It is almost impossible to fail to recognize it. It is easy of reduction.

Dislocation of the Clavicle. — Dislocation of the clavicle is rare. If it occurs, the common form is a dislocation of the acromial end upwards, with rupture of the ligaments. A rarer occurrence is dislocation of the sternal end of the collar-bone. All these dislocations are easy to recognize, can hardly help being seen. It is very difficult to press the bone back into place, and almost impossible to keep it there. The only one of consequence, as regards endangering life, is dislocation of the clavicle backwards behind the sternum, when it presses on the pneumogastric and on the trachea, and leads to dyspnœa and to severe symptoms. That accident is extremely rare. Something must be done to relieve it; and the most practical thing would seem to be to divide the fibres of the sterno-mastoid muscle subcutaneously, and endeavor to press the bone back into place. Failing of that, I suppose a resection of the end of the collar-bone, with antiseptic measures, would be proper and justifiable.

Usually dislocations of the sternal end are upward and forward, and do not entail any injury to the parts in the throat, but entail deformity, and subsequent bad use of the arm.

We try to force the bone and keep it back in place by strapping and pads, and especially by having the shoulder drawn back as far as possible, to draw the collar-bone out. Treatment is to be continued four to six weeks.

The ordinary dislocation of the collar-bone is of the acromial end upwards. The ligaments are ruptured, and the bone pulled up by the fibres of the trapezius muscle. And we find, on looking at such a patient from behind, a rigid line along the fibres of the trapezius, which is rather diagnostic of dislocation; and a projection, which, of course, would have to be diagnosticated from a fracture of the acromion process with drooping of the shoulder.

The treatment is about the same, whether it be fracture of the acromion process, or dislocation of the collar-bone. Crowd the arm well up, and strap the acromion down, and hold it in position four to six weeks. The results are fair. A little deformity frequently remains. The arm, however, becomes good and useful.

The other dislocations of the acromial end are rare. It is not worth while to waste much time on them. It may be dislocated a little forwards or backwards. The treatment would be about the same. Force the shoulder back; pad; and force the collar-bone down into place.

Dislocations of the Humerus.— Dislocations of the humerus are generally described as four in number. One is so extremely rare that we can eliminate it in speaking of treatment, and that is where the bone is thrown out of the socket and lodges back on the scapula. You may never see such a case. When it occurs the diagnosis is very easy.

The ordinary dislocation of the humerus is forward under the coracoid process, what is called subcoracoid. The bone comes out of its flat socket and slips forward, and a little downward, under the coracoid process, and rests between the coracoid and the ribs.

The other common dislocation is when the bone drops straight down and rests in the axilla.

Now in either of these two common forms, the roundness of the shoulder is lost. The natural shape of the deltoid muscle, instead of being rounded out, looks flat. If we seize the shoulder in this way, we are conscious of a vacancy, an empty space under the acromion process. We can compress the muscular fibres as we cannot do on the sound side. The arm appears to be slightly lengthened. Motion is lost. If we place the hand on the opposite shoulder and have it held, we cannot bring the elbow down in contact with the ribs, if the bone is out of the socket. We may force it down temporarily, and it springs up again. We can compare that with the sound side; and find that it is perfectly easy to have that laid down in its normal position. The loss of roundness of the shoulder; loss of mobility; loss of function, of course; and inability to approximate the elbow to the side, are the important points. In addition to this, if dislocation of the humerus happens to be downwards into the axilla, if we raise the arm from the side, and pass the hand well up into the axilla, we always find the head of the bone there. If there is any doubt, we can compare with the sound side; and can hardly fail to find projection downwards of the head of the bone. If there is subcoracoid dislocation, we can feel the head of the bone under the fibres of the pectoral muscles.

Obstinate abduction of the arm from the side; loss of motion, and disability, are common to the two forms of dislocation.

The patient having been etherized, and the muscles all relaxed, the obstacle to reduction would appear to be to get the head back through the capsule, through the rent by which it went out. In many cases this appears to be very easy indeed. Ether having been given, with a little traction and manipulation, the bone frequently slips back into place. Various manœuvres are contrived for that purpose. One secret in reducing dislocations of the shoulder is to render the scapula immovable; because if that moves with the humerus we lose all power of reducing the head. The scapula is rendered immovable by a strong bandage put around it and held by an assistant with great firmness. If that is not sufficient, additional immobility can be gained by applying some heavy adhesive plaster over the scapula, and drawing on the ends of that. The scapula secured; the arm is got back into place by various manœuvres. If, as is usually the case, it is in the axilla, then if the arm can be drawn down and the head forced up from below, it is easily pried into place. That is done by the surgeon's foot in the axilla, who sits beside the patient, draws upon the arm, and presses the head of the bone back into the socket. If this fails: having the scapula held, and drawing firmly off in the longitudinal direction frequently gets it into place. If this fails, the patient is etherized and placed upon the floor, and the foot of the surgeon is placed upon the shoulder, and the arm seized and drawn directly upwards, and that frequently succeeds.

Then there is the method called Kocher's, by which the arm is held firmly in to the side, and the bone rotated out and lifted into the socket. There is rarely a failure in one of these methods. Sometimes one succeeds a little better than the other; but the simpler one of pressing with the foot in the axilla is frequently successful. We are entirely sure that the bone goes in by hearing it, or feeling it, — by hearing a distinct snap when it goes in.

That is all the treatment. The trouble is to prevent it from dropping out. The capsule has been badly lacerated, and the joint is really no joint at all. It drops out very easily unless taken care of. The motion by which it will drop out is in lifting the elbow away from the side; hence, in the subsequent treatment, we must take great care to keep the elbow in to the side by a body bandage, and to put the forearm in a sling. With the humerus approximated to the ribs and the elbow supported, it is impossible for the head to drop out. That should be continued about a week, and then the arm put in a sling only. In some cases, where there have been repeated dislocations, it is a good plan to fasten an elastic around the arm and to the side, which prevents outward movement for many weeks.

It is a long while before the adult recovers full use of the shoulder. In lifting the arm to the head, or in making the motion of trying to put on a coat, it is long before either can be done without pain.

All dislocations are accompanied by great swelling, more so than fractures; consequently, after the injury is reduced, subsequent treatment should be very gentle. No very hard bandages should be put on. Frequently, evaporating lotions or leeches may be called for, and tight bandaging will not be borne. After the part has recovered, and the patient is left to himself, the

use of the arm may be much improved by gentle manipulations, massage, liniments, warmth, — agents of that class.

What we have to dread in any old person after dislocation is the chronic rheumatic arthritis that may be set up in the joint; and we cannot always predict that they may not afterwards have some stiffness or roughness of the joint, although the part may be perfectly restored to place.

Dislocations of the Elbow. — The elbow is a complicated joint, and the great point is this, when it is dislocated and you treat it, to be sure that both bones are back into place. It is very easy to appreciate, if the ulna is out, when it comes back into place with quite a loud snap. The joint is locked again, and the motions of flexion are restored and the symmetry of the arm; but the head of the radius is a small bone, its motions are peculiar, and it may not be perfectly reduced; and if it is overlooked, it is disastrous to the future use of the joint.

The books make a great many divisions of dislocation of the elbow. They are not, however, of very much importance. They are called backwards and inwards and backwards and outwards, etc., but, practically, they are all backwards, and more or less turned from side to side. The whole treatment consists in getting both bones back into position. The patient having been etherized, we go through the motions of having the fulcrum applied at the bend of the elbow, the arm steadily held, and the forearm first extended, and then brought up forward; and then, if we have restored the ulna, we may carefully look for the position of the head of the radius, and endeavor, by prying, pronation, supination, flexing and extending, to get that back into its normal position.

The diagnosis of dislocations of the elbow, of course, turns on the relative position of the three points, the two condyles and the olecranon, that we mentioned in speaking of fractures just above the elbow-joint. If they are in their normal position compared with the other arm, it cannot be dislocation; it is probably a fracture. If the ulna is drawn far out of its normal position as regards the condyles, then it is a dislocation. Of course the final test is in getting the arm in place and seeing whether it will stay. If it will, it is dislocation without fracture.

In all healthy subjects, and especially in young subjects, dislocation of the elbow is not followed by impaired use of the joint. It takes time, but motion is generally perfectly restored. It is not desirable to keep splints on too long. I think that is quite an important point. You must see in a joint so firmly locked together, that if it is once put back into place it is not very likely to get out again, and a confinement for a moderate length of time is all that is necessary; and after the synovitis is subdued, it is better that the patient should begin moderately the use of the arm. Cases have occurred, occasionally, in which, through fear of using the arm too soon, it has been tied up too long, and the consequence was that a simple synovitis has been converted into fibrous anchylosis; and then both physician and patient may be at a loss to know whether there had been a fracture or not; whether it would be safe to move the arm, and whether it would ever recover its mobility.

Very careful diagnosis from fracture. Very careful reduction of both bones back to their perfect position; then a short treatment afterwards, with the arm on the internal angular splint, and a sling; the back of arm uncovered, so that we can apply evaporating lotions or leeches; no tight bandaging being used.

Dislocation of the Wrist. — Dislocation of the wrist is almost unknown. Few people have ever seen one. It is accompanied with fracture, — fracture of the radius. Fracture of the radius and dislocation of the wrist, or Colles' fracture, is common. Dislocation of the wrist pure and simple is extremely rare. Of course, I would not include in this statement those cases of compound fracture where, from severe blows and laceration, individual bones of the wrist may be thrown out of place; but dislocation of one row of carpal bones from the other, or of a row of carpal bones from the articulation with the radius, is extremely rare.

Treatment would be obvious and simple. Draw it back into place and confine it on splints, and gradually use passive motion.

Dislocation of the Thumb. — Dislocation of the thumb, at the joint where the phalanx joins the metacarpal bone, is recognized as an extremely annoying dislocation. It is complicated by the fact that there are two little sesamoid bones; and when the thumb is thrown out, the phalanx goes down into the palm and gets entangled in the tendons. Make a fulcrum of your own left thumb under the joint, then pull the patient's thumb directly forwards, and then force it back beyond a right angle. It is difficult of reduction, and in some cases requires subcutaneous section of some of the fibres. It must never be allowed to remain out of place, because it does not give a good result in its false position; and, rather than leave it, we should divide the tendons, or even resect a portion of the bone and push it back into its place, and treat it afterwards as an excision, rather than leave it in a false position, where the thumb is practically useless and painful.

Dislocation of the fingers can be reduced by extensions and prying backwards.

Dislocations of the Hip. — They are four, of which one is excessively rare. Two are the common ones. These two which are common are merely modifications of each other. The head of the bone may go out of the socket and directly upwards and backwards upon the dorsum of the ilium, in which case it is called a dislocation on the dorsum. As a modification of that, it may not go up quite so far, may slip out and drop a little lower down into the sciatic notch. Dislocation into the sciatic notch and dislocation on the dorsum are practically the same thing, except in the amount of shortening. On the other hand, it may drop out and go directly down into the thyroid foramen, in which case the limb is a good deal lengthened instead of shortened. In very rare and exceptional cases it is thrown out and goes up upon the pubes, and rests either near the anterior spine, or upon the pubes itself. That, however, is excessively rare.

The ordinary dislocation in a strong person, who receives a violent injury, is dislocation upon the dorsum. Now this is so marked in its symptoms that it should hardly be overlooked. The limb is shortened from one and a half to two and a half inches, at once. There is not gradual shortening. Obstinate inversion of the foot to an extreme degree takes place, and the patient cannot in any degree turn it out. We have somewhat the characteristic appearance of a patient with old hip disease and dislocation on the dorsum,

which you are familiar with in that disease. If the patient is thin you may feel the head of the bone upon the dorsum by manipulation and examination; but if the patient is very fat and large, it is difficult to feel it under such a dense mass. On the other hand, we have two to two and a half inches of shortening, extreme inversion, total loss of motion about the part, and the history of a violent injury. This injury has to be of a peculiar character; and the blow to knock the bone out usually has to be received on the back of the trochanter, in some way, so that the moment the bone is knocked out and passes over the edge of the socket, the muscles seize it; and in ordinary cases pull it directly up; and in less violent cases pull it back; and, in exceptional cases where the blow is received from above downwards on the trochanter, it is conceivable that it may fall directly down into the thyroid foramen.

Great weights and heavy bodies striking the nates and side of the trochanter from behind are the usual causes of dislocation. The falling of timbers is a cause. I remember one case in which the cause was the falling of a sign from a building. The caving-in of earth occasionally, though that is more apt to make a crushing of the pelvis. If the bone is thrown out of the socket into the sciatic notch, the shortening is about one-half as great; the inversion is just the same; but the foot is turned over the toes of the opposite foot, instead of over the dorsum. Total loss of function, and the other signs, are the same.

If, by any chance, the bone is knocked down into the thyroid foramen, it is lengthened and turned outwards and partially flexed, and is very characteristic in its appearance. If thrown up upon the pubes, we have shortening, but the toes usually turned more or less outwards, and partial flexion and abduction occur.

Of course, profound etherization is the first measure. Then the patient had best be treated on the floor, or some firm place, low down, where the surgeon can stand over him. A thin mattress or blanket spread on the floor is sufficient. It is essential here, in manipulating to reduce the dislocation, that the pelvis be held still; just as in trying to reduce a dislocation of the humerus, the scapula should be held still. This is to be done by an assistant kneeling and compressing the rim of the pelvis firmly on both sides, while the surgeon makes his manœuvres. The pathological phenomena of dislocation upon the dorsum, or into the sciatic notch, are about the same. The muscles are relaxed by ether; but the Y-shaped ligament is wound about the head of the bone, and the bone will not go back until it is relaxed and unwound; hence bend the thigh gently upwards and turn it in towards the abdomen, and then the surgeon takes the lower leg as a fulcrum, and rotates the head out, and lifts it into place. This generally succeeds the second time, if not the first. Flex, adduct, abduct, rotate and lift, is the brief rule.

It occasionally happens, to the annoyance of the operator, that in reducing a dislocation upon the dorsum he fails, unlocks the ligament, gets the bone almost back into place, but instead of gliding into the socket it then slips down, and he has converted a dislocation upon the dorsum into a dislocation in the sciatic notch. In that case he has to repeat his manœuvres, and lift more forcibly over the edge of the socket.

In the dislocation into the thyroid foramen, the reverse manœuvre is to be brought about to unwind the ligament and get the bone to slip back into place. A great deal of time might be spent in illustrating this to you; but it is done so much better and more perfectly in Dr. Bigelow's monograph on the subject, that I advise you to look at his photographs, and the position of the ligaments, and the manœuvres.

Dislocation of the hip is rare. It is of immense importance to recognize it, and to reduce it within the first few hours after the injury; there are two common forms, dislocation into the sciatic notch and upon the dorsum, easily recognized by their peculiar deformity. Ether gives immense assistance in the reduction; and these manœuvres never, I think, fail of success in getting the bone back.

The subsequent treatment is important. In order to prevent the bone from slipping out again, everything being badly lacerated, it is best to make a splint of the other leg; and the knees should be firmly bandaged together, and the patient kept on his back. The patient should be kept in bed two or three weeks, before he is trusted to move the leg out. It will be swollen and painful; and it will take a good deal of time before he will recover the utility of the part. When he has partially recovered, rubbing, massage, etc., may be used. Here, again, in the elderly person, we may have to treat chronic rheumatic arthritis; but, on the other hand, it is fair to say that dislocation of the hip in the old person is not common at all; for the injury, if received, is almost sure to break off the neck of the femur, instead of putting the head of the bone out. Dislocations of the hip are most common in young persons; and in very powerful vigorous men, men in the prime of life, who receive violent injuries.

Dislocation of the Knee. — Dislocation of the knee is almost unknown, excessively rare. Pathologically it is common: but as a traumatic injury, unless accompanied by compound wounds, opening into the joint, or by breaking of the bone, it is extremely rare.

The semilunar cartilage, which is fastened on the head of the tibia and deepens the socket for each condyle, is occasionally displaced, with very serious consequences; and it is best, perhaps, to allude to that a little more at length. The patient feels something slip about the knee; tries to manipulate it and get it back into place, and finds he can do everything except straightening. In addition to that he may notice a little thickening or projection just at the line of the joint. It is a displaced semilunar cartilage. It is pushed out over the edge of the tibia and caught in the joint, so to speak. If not recognized, it stays there. It is practically incurable. Nature accommodates herself to the new condition; and the patient is left with a partial stiffness of the knee, and inability to make perfect extension.

It is important to be recognized; and can be readily cured, if recognized. The patient should be thoroughly etherized; the leg flexed far back, and snapped back into place with extension; the semilunar cartilage, in the large percentage of cases, will slip back into place. Then keep the limb perfectly straight on a ham-splint; and later, begin to use passive motion to restore the joint. It is a quite common accident, and requires care in its treatment.

Dislocation of the Ankle. — The ankle can hardly be dislocated without fracture of one, or the other, of the sides of the mortice which hold it in. Fracture of the

fibula, with rupture of the internal lateral ligament, makes dislocation outwards; and the treatment to reduce the fracture, and set the parts, reduces the dislocation.

Dislocation of the Astragalus. — Occasionally the astragalus, which lies between the tibia and os calcis, is knocked out of its position. You can see that it must be a very peculiar injury to do it. Usually, the patient falls from a height, and alights upon the edge of something like a brick or stone, and strikes in the arch of the foot. In that way, occasionally, the astragalus is pried out of place. The important point to speak of in this connection is not the diagnosis. That is very easy, for the parts are superficial. By manipulation, we find that there is no crepitus and no fracture. The important point to speak of is the excessive difficulty of reducing this; and the disastrous effects, if left unreduced. So that after the patient has been etherized and attempts at reduction fail, it is considered better to excise the bone, rather than leave it in its false position. Possibly, cutting down to excise it, and dividing some fibres, may enable us to slip it back into place. But if that cannot be done, it had better be excised, and the cavity allowed to fill up; and with a shortened leg and a shortened foot, the patient will usually get along well. On the other hand, if the bone is left out of position and attempts at reduction fail — I have seen several cases — and, in fact, the universal testimony of surgeons is, that you have a very useless foot, and also a very painful foot. The patient walks lame, and with extreme difficulty. He is liable to ulcerations and necrosis of the bone; has not motion of the joint, of course; and is crippled worse, almost, than with amputation of the foot. So that in this rare injury it is better to etherize; then to manipulate; then to make a few cautious incisions, and subcutaneously to divide some of the apparently resisting parts. If those things fail, it is wiser to really excise the bone than leave it in its false position.

A word more that I did not mention under fractures. You must be very careful not to mistake a fracture of the surgical neck of the humerus for dislocation. That mistake has been made a good many times. You may judge how disastrous it would be to go through the motions to reduce a dislocation, and apply force to a fracture, when there was really no dislocation at all. It all turns upon this, of course, whether the injury is below the head of the bone in the neck; or whether there is absolutely a vacancy between the acromion process and the head of the bone. That point settled, the rest of the diagnosis becomes easy.

It is hardly worth while to take up time by considering the extremely rare cases where fracture and dislocation coëxist. There are such cases. When recognized, the treatment is, of course, extremely difficult. We are usually advised to endeavor to put the fractured parts into position, and to allow time for union; and then make a cautious attempt to get the head of the bone back into place in the socket. It is obviously impossible to do this until we have some leverage and fulcrum on which we can push back. A very important question is, sometimes, whether it would not be wiser to excise the head of the bone, and leave the patient with an excised false joint, rather than to risk the loss of mobility which we shall get by having a fracture united, and the head of the bone lying out of the socket.

SECTARIANISM IN MEDICINE.[1]

BY E. R. CUTLER, M.D., WALTHAM, MASS.

DEFINITIONS.

I DO not find in any dictionary or book of synonyms what I consider a full definition of the word "sect"; and, while I do not claim to be superior to these authorities, I shall, nevertheless, define it to be "a subdivision within a larger body having an organization and a distinctive name and creed." The word "school" would be its nearest equivalent. This is well defined to mean the "followers of a teacher or the adherents of a system of doctrine." Compared with "sect" this word does not so forcibly carry the idea of organization and separation. It is too broad and dignified a name to characterize the small and diminishing differences among classes of medical men. Therefore, I shall use the word "sect" and its derivatives as the most convenient and appropriate ones. By sectarianism I mean devotion to the interests of a sect or party as opposed or superior to those of the whole body.

CAUSES OF SECTARIANISM.

That there are sects, and that there is sectarianism, in medicine requires no proof. That their existence is an opprobrium I think also needs no proof. I think they are a scandal and an anachronism. In medicine they have no right to exist. So far as we are sectarian we are unscientific. Science is knowledge. Sect, wherever found, is based on ignorance or imperfect knowledge. It may be sustained and perpetuated largely by prejudice and partisan feeling, but its ultimate ground is uncertainty about fundamental facts.

Sectarianism in religion is difficult to deal with, because it is founded upon events long past whose occurrence can never be absolutely verified, and upon documents which are claimed to be of a miraculous and divine origin. Such a claim at once puts them beyond the efficient application of scientific criticism. Neither history nor philosophy can ever furnish irresistible proof on these subjects. If they could, they would long ago have done so, for a multitude of the best equipped men have given themselves to the task since the beginning of the Christian era. The result has been confusion worse confounded; and the only possible hope of an organic union of Christian sects is in mutual concession. Whether such union will ever come about I will not venture to predict; but every one will admit that the present condition is one of reproach and weakness to the church.

Among religious denominations it appears to be true that the smaller the difference the greater the antipathy.

In medicine, however, there are no essential reasons for sectarianism. In the first place, minor differences do not constitute mutual incompatibility; in the second place, the art of healing depends upon facts and principles which are intrinsically capable of scientific and logical demonstration. I do not say that such demonstration has yet been achieved, but its achievement is not hopeless or so remote that the present generation may not set itself about realizing it.

The evil of sectarianism is specially flagrant in this land of liberty where each thinks and acts as he pleases up to, and often beyond, the limits of social safety, and where each is accustomed to consider his own opinions as good as those of any one else.

[1] Delivered before the Middlesex South District Medical Society.

An important reason why sects flourish so here is the comparatively backward state of scientific attainment.

These divisions are further promoted by the ridiculous multiplication of medical schools, which absolutely insures a low standard of knowledge among both teachers and scholars, as well as the propagation of personal and sectarian opinions unmodified by the corrective power of broad and varied instruction and experience.

It is claimed by the adherents of homœopathy that its comparative failure in most of the European countries is owing to the prevalence of the military and despotic elements in their governments, which are largely in sympathy with the old medical organizations; also that prejudice and tradition have a far greater power there than here. I think there is little force in this claim, as is shown by the fate of Koch's treatment of tuberculosis, a measure which it might almost be said was promulgated by the government itself. As you know, this was immediately subjected to the most rigorous tests and, almost in a twinkling, mercilessly strangled in its very birth-place, to the great chagrin of its author and the minister of public instruction. The great enemy of homœopathy is the scientific spirit which demands irresistible proof, and which is much more highly developed in Europe than in America.

EVILS OF SECTARIANISM.

(1) The profession is put in a discreditable light before the public. Of course, the public is mistaken in regard to the merits of the case, but this is not to be wondered at. Our profession itself is greatly to blame for the situation. Instead of recognizing the right of every man in it to hold and apply in practice any opinion which commended itself to him, it has adopted the ecclesiastical method of persecution. It has adjudged certain lines of theory and practice to be heresy, and has treated those adopting them in the true mediæval spirit with professional ostracism. Instead of patiently opposing error with argument and fact, which would certainly overcome it in the end, it drove the heretics from its fellowship beyond the reach of persuasion or conviction, thus virtually compelling them to set themselves up into sects which have now become so well organized and established that they occupy the position of very respectable rivals, and enjoy the support and sympathy of multitudes who care little for their special practice, but regard them as martyrs to our bigotry. Then, as if to insure them the full advantage of their position, the members of the profession very generally allowed themselves to be called by a distinctive and sectarian name, thus reducing themselves to the same ethical level. Thus, while the homœopath gloried in and profited by his title, the rest of the profession, in this country at least, found itself almost compelled to accept the ridiculous denomination of allopaths. Of course, this has been, especially of late, generally disallowed; but it is still freely used by the public, and even if we do insist on the somewhat more respectable title of "regulars," we are still looked upon as only a larger sect. Thus the whole vantage-ground of professional dignity and unity was lost; and what was really (at first) a simple diversity of professional opinion came perfectly naturally to be regarded by the people generally as a mere factional quarrel which resulted in the larger body turning out the smaller one for mere opinion's sake. I say the fault is not so much with the people as with the profession; and great numbers of medical men have not even yet become possessed of the idea that there is nothing reprehensible in any mere opinion or practice, but only in the public announcement of the same for the purpose of securing patronage, which is essentially quackery.

This distinction was never made clear enough.

The by-laws of the Massachusetts Medical Society specify as a qualification for membership preliminary to examination by the censors, "that he does not profess to cure disease by, nor intend to practise, spiritualism, homœopathy, allopathy, Thompsonianism, eclecticism or any other irregular or exclusive system generally recognized as such by the profession or declared so by the councillors of said Society."

I think the result of the application of the above rule and similar ones has been only to divide and weaken the profession, to obscure the real distinction between honorable practice and charlatanism, and to make the latter easy and respectable for thousands of men who could not maintain themselves in open and unrestricted competition. So I say the profession is put in a discreditable light before the people, who think it consists of two or more rival sects, one of which is bigoted and intolerant, while the others are just as good and just as successful, and ought to be encouraged and championed. Our attitude before the people is all the time explanatory and defensive, and our ethical point so fine that our would-be defenders cannot see it distinctly or maintain it heartily. The public naturally takes the side of the apparently persecuted party; and its material support goes with its sympathy, to the detriment of persons and institutions which need both. Nothing can appear more puerile to disinterested observers than personal animosity or mutually antagonistic organizations based on diversity of opinion or practice within a great profession. Of course, it should be said, on the other hand, that nothing can be more contemptible than truckling to lay prejudice, or appealing a strictly professional question, like that of therapeutics, to the public, as is done when a name or a creed are openly announced and patronage bid for thereby. The public, however, sees no harm in this; and as the general profession has failed, at least until lately, to make the point plain, it still suffers in public estimation.

(2) Under the policy of non-intercourse set up by us on this insufficient ground, mutual enlightenment, reconciliation and assistance are impossible. A free discussion within the profession would long ago have resulted in the total annihilation of Hahnemann's preposterous theories concerning the nature of disease and the power of drugs. They were promulgated before modern science even had its birth, and before its present powerful and precise implements of research had been even discovered. They can only survive, I think, where sectarian walls shut out the light.

On the other hand, it does not follow that because some of Hahnemann's theories were to the last degree grotesque and his practical conclusions thereby invalidated, therefore all that he and his followers believed is false.

The central idea of the system *similia similibus curantur* was not original with Hahnemann, and in the judgment of many competent and unprejudiced men still furnishes a clue to valuable means of cure, especially in functional diseases.

Homœopathic practitioners could not attain their present measure of success if their creed was wholly a delusion. It is idle to ascribe it entirely to their surreptitious use of material doses of medicine under allopathic or empirical indications or to the unaided powers of nature. The evidence of the firm belief of these men in their theory is furnished by their great enthusiasm for it, and the fact that they seldom or never abandon it. Furthermore, many items of strictly homœopathic practice have been approved by teachers like Ringer and Bartholow, and generally adopted by the profession.

That many medicines when given in large doses produce effects directly opposite to those of small doses is well known.

If a substance is shown by experiment to act specifically and powerfully on certain organs or tissues, it is reasonable, at least in the absence of better means, to try small doses of the same substance in disorders of those parts. Of course, this is simple empiricism, and a homœopath would smile with contempt at it; but nevertheless I believe it is the sole basis of a reasonable and successful homœopathic practice. Again, the minute subdivision of medicines, though sometimes carried by homœopathists to a monstrous degree of absurdity, may be a useful preparation for speedy absorption and therapeutic action, and is being utilized by our best pharmacists.

If these items of homœopathic theory and practice are of value, they ought to be in the possession of the whole profession; and the latter is the loser to the extent of their value, under the policy of non-intercourse.

Of the loss which accrues to the homœopathic practitioners themselves from lack of association with the rest of the profession, I need not say much. It is evident that their theories lead them away from pathological anatomy, from the physical diagnosis of disease and from its local, mechanical and surgical treatment, while the latter is widening its scope with great rapidity.

Think of the inroads which these and other lines of treatment have made, and are yearly making, into the territory of drug-therapeutics, even among homœopaths. Without going at all into detail, let me simply mention electrotherapy, hypnotism, massage, hydrotherapy, radical and palliative surgery — as applied within a few years to effusions into normal cavities; to obstruction and perforation of any part of the intestinal and biliary tracts and to many other abdominal lesions; to gonorrhœal, puerperal and tubercular infections of the pelvic organs and joints; to ectopic gestation; to tumors and injuries of brain and cord; to plastic operations on the cervix uteri and perineum; and to diseases of the eye, ear, nose, skin, etc.

Our homœopathic friends also certainly run great risk — to say the least — of being led by their faith in drug-treatment into serious and fatal mistakes and delays.

The difficulty in deciding when a case ceases to be a medical one and becomes surgical is often very great, and the decision critical. The temptation to continue medicinal treatment when the alternative is a serious surgical operation, is very strong, especially if one cannot perform the operation and flatters himself that he is guided by the one and only true therapeutic law.

The tendency to neglect the pathological diagnosis, not required for average homœopathic treatment, in favor of the easier symptomatic one is a serious weakness; for, if for no other reason, the whole vast subjects of the hereditary transmission of disease, and private and public prophylaxis against infections which destroy the larger part of the human race, depend upon it; and I believe that the time will come when a successful scientific treatment will depend on it.

In fact, I think it is evident that the homœopaths must of necessity be guided more and more in their treatment by the pathological condition of the patient, as discovered by physical examination, that is, by the objective signs of disease rather than by the patient's feelings, which constitute its subjective symptoms. These latter bear no constant relation to the former; so that if one is guided by them, he may be treating very diverse conditions or processes by the same remedy or, *vice versa*, applying entirely different medicines to the identical pathological process. This may be correct and successful homœopathic treatment, but it sounds highly irrational to the unsophisticated; and it seems certain that a really accurate knowledge of the pathology of disease, such as science is determined to seek and find, must create scepticism as to the value of remedies whose indication is sought in the patient's feelings. Now all the means of diagnosis are employed by homœopaths, and their use taught in their schools. The stethoscope, the thermometer, the microscope, the test-tube, the speculum, etc., as well as our unaided eyes and fingers, are all means of reaching a little nearer the essential condition than the patient's statements would carry us; and they tend to supplement or even supersede these and guard against erroneous conclusions unavoidable if guided by them alone.

True we have not penetrated into the secrets of the essential nature of the pathological, any more than the physiological process; but it is an enormous gain which bacteriology and chemistry and microscopy have already secured in that direction.

All these things must inevitably tend straight away from reliance on mere symptomatology; and our homœopathic friends cannot resist the tendency if they try. That they will necessarily use all these pathological gains of pure science is shown by the fact that they have always used such as they have had.

It seems to me that in these ways, narrow and sectarian views, especially when met by a supercilious opposition, are the source of serious loss to medical men of all persuasions.

(3) Useful legislation is prevented.

Suspicion and jealousy are easily aroused among the sectaries if any measure, State or National, is proposed by the non-sectarian part of the profession; they fear that it may in some way minimize their influence or antagonize their party interests. On the other hand, their factious insistence on the use of the highly and justly obnoxious sectarian title drives many high-minded men into an indignant and even arrogant refusal to have anything whatever to do with them. Thus effective co-operation for securing general legislation is prevented. I have been assured by a prominent lawyer that a bill to regulate medical practice and banish from the State the quacks who infest it in such numbers could easily be passed if the whole profession would unite in urging it.

The American Institute of Homœopathy adopted at a recent meeting a preamble and resolution reading as follows: "Whereas the creation of a single-man power in the person of a Medical Secretary at the seat of government is likely to interfere with the personal rights of both physicians and people, *Resolved*, that

the American Institute of Homœopathy disapproves of all efforts on the part of our National Congress to erect authoritative medical standards by the appointment of a medical health-officer in the president's cabinet."

I am by no means certain that the plan of establishing such an office is wise; but the above resolutions were evidently dictated by the fear that it might be used to the disadvantage of homœopathic practitioners.

It is, I think, pretty generally recognized that medical instructors should not have the power of licensing their graduates to practise, but that it should be vested in some central examining board. Such boards exist in some States; but they have failed of establishment in Massachusetts because the power of the quacks has been reinforced by the influence of medical men.

(4) Hospitals suffer.

In all that I have said there is nothing new. You are all familiar with these things; and, while I have long been deeply sensible of the unfortunate condition of the profession, I should probably never have written a word on the subject, or changed my personal attitude toward homœopathic practitioners except for one circumstance, namely, the acute phase of the trouble produced by the springing up of hospitals in our small cities. The bearing of these hospitals on professional relations is very direct; and a few words to this point will develop the special purpose of this paper. The small hospital, growing with the growth of the population around it, and adapted to its wants is, with us in Massachusetts, a new institution. It is a part of the general socialistic movement of the day. It is made possible by the great expansion of the surgical field, not only in traumatic but especially in pathological cases, by the rapidly increasing willingness of the people to enter it for treatment, by the service of trained nurses, by the great facilities it offers for the securing of aseptic conditions.

It sometimes begins its beneficent work with small or no endowment, and depends largely on the personal interest and effort of its friends; and, in order to thrive, it should have the undivided and enthusiastic support of all the people. They should all feel a pride in it as one of their cherished local institutions. All causes of difference and bitterness should, if possible, be removed from among those who should favor and help it. Now just here the homœopathic question comes to the front; and it must be squarely met, or evaded by some indirection. It has been met in different ways in different places. In the large cities hospitals have been established and carried on upon an openly partisan basis. This existence of mutually exclusive institutions is a discredit to the profession, a vexation to the public, and a loss to both; but as the means for it are forthcoming, it is steadily continued.

There are now forty hospitals expressly homœopathic in the larger cities of the United States. In sixteen of these places are also professedly homœopathic medical schools; and in all of them and many others are homœopathic medical societies.

These institutions place almost insuperable obstacles in the way of organic union of the profession in these cities. But in the small places these outward difficulties do not exist, and the local conditions call loudly for co operation. At the present time the tendency in such communities is steadily toward the explicit recognition of medical sects in the by-laws of the hospital.

To show how important this matter is, and how inevitably and rapidly it must become a vital concern to the whole profession, I shall cite the following facts and figures. I omit from consideration, be it understood, all the hospitals of Boston and a considerable number elsewhere which are limited in their scope or supported by large endowment. I include only small, general hospitals supported by the people about them. But of this class I have given all in the State of Massachusetts as far as I know.

These hospitals are initiating a new phase of professional experience. They are greatly helping to raise the standard of professional work. They strongly favor a laudable professional ambition and pride. They are making the rural profession to a degree independent of the city expert and specialist, without serious detriment, I believe, to the public health.

The advantage of service in the metropolitan hospitals and teaching in the metropolitan medical schools alone gives these experts their superiority. No doubt they will continue to maintain it by these means, and this is as it should be. We need them in cases of unusual doubt or difficulty, and we cheerfully recognize their ability to help and instruct us. But we do not need to send them all the plums; and we do owe it to our respective constituencies to spare them the expense of imported advice and skill as far as we can, especially when they are generous enough to furnish us with the means of doing our own work well and improving ourselves thereby.

I think that in trying to enlist the humanitarian impulses of the people on behalf of the inmates of the hospital we may possibly fail to think and say enough about the advantage accruing to the doctors, and to the community outside indirectly, in the cultivation of their skill and self-reliance by the local hospital. This advantage is indeed no trifling one, nor one to be kept out of sight or made light of.

Our profession ought to make the most of every means for its own elevation and improvement.

It ought to be such that the people would look up to it as a strong, united and influential body, able to instruct and lead in all matters concerning public health and education as well. It is far better for the people that the average of professional accomplishment should be high, than that there should be a small number of medical men head and shoulders above the rest.

Now I claim for the hospital that it is, or should be, one of the very important agencies for this general advancement of the medical profession, if all are allowed to share its advantages; or, on the other hand, it may aggravate and perpetuate invidious distinctions among classes and individuals if its privileges be limited to a few.

The hospital should be the pride of the profession, whose members should have free access to it for their patients and their work. There, at least, they should be ashamed to be guilty of negligence or slovenliness in diagnosis or treatment; there they should always find free and friendly assistance and advice; there they should see all those things done which could reasonably be expected of the local practitioners; and there should be made manifest who were most worthy of staff appointments. The hospital should be a sort of medical exchange.

The profession should be largely represented on its list of corporators, its trustees and all its working committees.

It should be understood that the doctors are capable — more so than any one else — of managing a hospital.

The hospital need not, and should not, assume the responsibility for the results of any cases except those treated by its staff; and, to protect itself, this latter should be small in numbers and composed of the very best men within reach. The staff should not monopolize the work.

Of course, they should receive no remuneration for their official work; but for all other work either they or other physicians should be paid by such patients as are able to do so after meeting the usual hospital charges. Very many cases go to the metropolitan hospitals because they can there secure the best attendance for nothing, to the loss of doctors elsewhere. On the other hand, many cases are treated at home, to their detriment, which would go to hospitals if the attending physician did not wish to retain his fee. Let him freely use the hospital to the mutual advantage of himself and patient, their financial relations being the same as before, except that the hospital must have prior claim. The one essential point is, let no man enter the hospital as a sectarian.

So much for Utopia. Now for Massachusetts.

(To be continued.)

THE COMPLICATIONS OF SCARLET FEVER AS OBSERVED IN FIFTY CASES.[1]

BY HENRY JACKSON, M.D.,
Physician to Out-Patients of the Boston City Hospital.

THROUGH the kindness of Dr. Shattuck I had the opportunity of taking charge of the contagious service of the City Hospital last January. During this time 53 cases of scarlet fever were under my care for a part of their stay in the hospital, and many of them presented various complications, which offered a most interesting opportunity to study the various phases of this disease. The study of these cases was to me a source of much profit and interest; so that I feel a review of the month's work, with such conclusions as I can draw, may interest the members of this Society.

There is perhaps no disease whose course is more varied, or in which the possible complications may lead to more serious results, than scarlet fever. If the disease runs the usual course without any complications, it is mild in character, the only serious symptom being the prolonged desquamation, which demands absolute isolation of the patient on account of the danger of spreading the disease. Unlike measles, it is pretty satisfactorily demonstrated that the disease is most contagious during the stage of desquamation.

The cases under observation in January were of especial interest on account of the large number which presented serious throat lesions, as manifested by a membranous deposit in the pharynx or nose-pharynx: cases often spoken of as diphtheria complicating scarlet fever. But, as I hope to demonstrate to you, a careful clinical observation of these cases and a bacteriological examination as to their etiology proves that the membranous deposit seen in scarlet fever has no connection with diphtheria except a close anatomical resemblance, and even here there are, in many cases, well-marked pathological differences.

[1] Read at the Boston Society for Medical Improvement, April 24, 1893.

During the last seven years the following cases of scarlet fever have entered the City Hospital:

	Cases.	Died.
1886	42	2
1887	75	9
1888	93	6
The contagious service was opened in February, 1888.		
1889	42	0
1890	103	4
1891 to January 31, 1892 } with diphtheria,	137	6
	20	11

I give a summary of 53 cases, which I intend to report in detail as to the occurrence of various complications. They entered the hospital during the months of December and January. Where the history was obtained the eruption followed the onset of the first symptoms, as given below:

1 day	20 cases.
2 days	1 case.
3 days	1 case.

In three cases a membranous deposit appeared on the tonsils two days before the eruption. In two cases a membranous deposit appeared on the tonsil three days before the eruption. In one case, which a bacteriological examination showed was not diphtheria, the membrane was observed on one tonsil one day before the appearance of the eruption, though at this time there was a scarlet macular eruption on the hard palate.

Age of patients.

	Cases.
7 mos. to 2 years	3
2 to 5 years	15
5 to 10 "	20
10 to 20 "	12
20 to 30 "	3

Total, 53 cases. One-half the cases between 2 and 10 years.

Complications and Variations from usual symptoms.

	Cases.
Membrane in throat	20
Otitis media purulenta	9
Primary albuminuria (all with high temperature)	3
Nephritis later in disease	6
Abundant vesicular eruption in addition to usual scarlet rash	3
Lobar pneumonia	3
Widespread bronchitis and probably broncho-pneumonia, 3-5	
Elevation of temperature later in desquamation without any assignable cause	7

Desquamation was completed

Average (37 cases)	in 54 days.
Longest	in 70 days.
Shortest	in 32 days.

Mortality, 11 cases.

	Cases.
Septic naso-pharyngeal disease	8
Spinal caries (infant.)	1
Acute nephritis (uræmia)	1
Moribund on entrance (no history)	1

If we throw out the case of spinal caries, which died many weeks after recovery from the scarlet fever, and the case moribund on entrance, we have a mortality of 9 cases in 51, in all but one of which the death was the result of intense general septicæmia, secondary to a foul naso-pharyngeal disease.

Of the uncomplicated cases none were very sick and none died. The chief interest centres in the cases complicated by membranous deposit in the throat, 20 in number, and these I wish to give in detail.

CASES COMPLICATED WITH MEMBRANE IN THE THROAT.

Case I. A boy three years of age.

Time. Entered the hospital on the third day of the disease. The tonsils were enlarged, and on each was a well-defined gray patch; several small patches on the soft palate. The throat was clear in seven days.

Rash. The eruption was faint, and soon faded.

Complications. In the fourth week there was albumen in the urine and numerous casts, with many free blood-cells.

Result. Discharged well on thirty-seventh day. No septicæmia.

Case II. A boy fifteen years of age.

Time. Entered the hospital on the third day of the disease. The tonsils were enlarged; on each was a dirty gray patch.

Rash. Bright in color and well marked over whole body; high fever at first, with primary albuminuria.

Complications. None.

Result. Discharged well on seventieth day. No septicæmia.

Case III. A girl of nine years.

Time. Entered the hospital on second day of the disease. Both tonsils enlarged and covered with a thin gray membrane, which extended over the posterior pillars. On the fourth day the throat was practically clear.

Rash. A marked scarlet eruption.

Complications. In the fourth week there was a trace of albumen in the urine and a few casts of the hyaline variety.

Result. Discharged well on the fifty-sixth day.

Case IV. A woman twenty years of age.

Time. Entered the hospital on the third day of the disease. Tonsils enlarged, red, with prominent follicles; on the right tonsil there was a small gray patch.

Rash. Well marked.

Complications. None.

Result. Discharged well on forty-second day. No septicæmia.

Case V. A man twenty-three years of age.

Time. Entered the diphtheria ward. Tonsils swollen and red; on right tonsil several white follicular plugs, on the left tonsil a small white membrane and a small white patch on the left posterior pillar. In ten days the throat was practically clear. No rash.

Rash. On the second day a scarlet macular eruption appeared, which was followed by desquamation. In this case the question must of course be raised whether the scarlet fever was not a secondary disease implanted upon a preëxisting throat affection, but the eruption appeared so quickly that I am inclined to consider that the throat affection was but a complication of the scarlet fever, the eruptive stage being delayed.

Complications. None.

Result. Discharged well on the forty-fourth day. No septicæmia.

Case VI. A boy fifteen years of age.

Time. Entered the hospital on the third day of the disease. The tonsils were red and swollen, and on each was a patch of gray membrane. In four days the throat was practically clear.

Rash. Moderate; and on entrance, the second day of the rash, already fading.

Complications. None.

Result. Discharged well on the forty-second day. No septicæmia.

Case VII. A boy three years of age.

Time. No history obtained. There was a purulent discharge from the nose; the whole pharyngeal cavity was covered with a thick white tenacious membrane. The breath was fœtid.

Rash. The eruption was fading and desquamation was beginning.

Result. The child failed rapidly, and died on the fourth day after entrance. There was from the first a marked septic condition; pulse rapid and feeble; temperature high.

Case VIII. A girl seven months of age.

Time. Entered the hospital on the third day of the disease. Foul purulent nasal discharge. Both tonsils were covered with a thin, gray membrane; there were gray patches on the uvula and soft palate. Clear in seven days.

Rash. A faint macular eruption over whole body.

Complications. The purulent nasal discharge continued after the membrane disappeared from the throat. In the second week a double otitis media purulenta developed. In the fourth week there was a rapid rise of temperature, caused by a pneumonia of the left lower lung, and the child died in four days.

Result. Death from pneumonia on the twenty-fifth day.

There was a marked general septic condition from the first.

Case IX. A girl six years of age.

Time. No history obtained. Both tonsils enlarged, and on the right tonsil was a gray patch, which extended over the posterior pillar.

Rash. On entrance there was an intense scarlet rash; for two days there was a high temperature and slight albuminuria.

Complications. None.

Result. The patient was discharged well on the fiftieth day. No septicæmia.

Case X. A woman twenty-four years of age.

Time. Entered the hospital on the third day of the disease. Both tonsils moderately enlarged, and on each there was a thick gray membrane. On the fourth day the left tonsil was covered with membrane, which extended on to the anterior pillar. On the uvula and soft palate there were small patches of membrane. In four days the throat was almost clear.

Rash. Bright-red scarlet eruption.

Complications. In the second week the pulse was weak and irregular; the heart was not enlarged, — a systolic murmur at the apex. The unfavorable condition of the heart was transitory, passing off in a few days under absolute rest and small doses of digitalis. Convalescence was somewhat prolonged.

Result. The patient was discharged well on the fiftieth day. No septicæmia.

Case XI. A girl six years of age.

Time. No history. Membrane on both tonsils and uvula; patches of membrane on the soft palate.

Rash. Well-defined scarlet eruption. Purulent nasal discharge.

Complications. Throughout both lungs sibilant and sonorous râles, and in patches fine crackling râles, suggesting the existence of lobular pneumonia.

Result. Died in two days. Marked septic condition, with rapid and feeble pulse.

CASE XII. A boy thirteen years of age.

Time. Entered the hospital on the second day. An ulceration on the right tonsil and a small gray patch on the right side of the uvula, which had considerably swollen.

Rash. A moderate eruption.

Complications. None.

Result. Discharged well on the forty-second day. No septicæmia.

CASE XIII. A boy seven years of age.

Time. Entered the hospital on the third day. Both tonsils and both sides of the uvula covered with membrane. In seven days the membrane had disappeared.

Rash. Moderate in character, with a few vesicles.

Complications. In the fourth week otitis media left ear. A few days later acute nephritis developed, with marked diminution of the urine. Vomiting ensued, and he died in one week with uræmic convulsions.

Result. Death from nephritis, thirty days. No septicæmia.

CASE XIV. A girl three years of age.

Time. Entered the hospital in diphtheria ward. On left tonsil there was a patch about the size of a finger-nail. Three days later a scarlet rash appeared, with moderate rise of temperature. The late appearance of the rash of course suggested that the scarlet fever was a secondary disease, not associated with the primary throat lesion. Eruption slight.

Complications. In the fourth week acute nephritis with general œdema developed. Desquamation ceased on the fifty-sixth day, and she was transferred to the medical service on account of the nephritis which still existed. No septicæmia.

CASE XV. A girl two years of age.

Time. On entrance to the hospital she was desquamating. Both tonsils, uvula, pillars of the fauces and posterior pharyngeal wall were covered with a gray membrane. There was a foul purulent discharge from the mouth and nose. The edges of the nostrils and the lips were cracked, bleeding, and partially covered with scales. A bacteriological examination of the discharge showed streptococci and saprophytic organisms; no bacilli of diphtheria. The throat gradually cleared up, and her condition improved.

Complications. In first week otitis media purulenta. Fine bronchitis, probably lobular pneumonia.

Result. Discharged well on forty-second day. There was from the first a marked septic condition, as indicated by the rapid, feeble pulse, irregular temperature and the bad general condition.

CASE XVI. A girl of six years, sister of No. 15.

Time. On entrance to the hospital both tonsils, uvula and pillars of the fauces covered with membrane, which extended on to the posterior pharyngeal wall. Purulent nasal discharge.

Rash. A moderate macular eruption which faded in three days.

Complications. Dulness and fine râles in the right lower back. Coarse and fine râles through both lungs. On the sixth day double otitis media purulenta.

Result. Died on the seventh day.

There was a marked septic condition from entrance. Anatomical diagnosis from autopsy by Dr. Councilman: Acute bronchitis and broncho-pneumonia, acute spleenic tumor, acute endocarditis, acute nephritis, septicæmia from general infection of streptococci.

CASE XVII. A boy of seven years, brother of Nos. 15 and 16.

Time. Entered the hospital with the history of sore throat for three days. Three days previous his two sisters had entered the hospital, one with a fully-developed scarlet fever eruption and one in the stage of desquamation. On the hard palate was a bright red macular eruption as is seen on the day before the appearance of scarlet fever. The boy was bright and said he did not feel sick. On the left tonsil was a patch of membrane, and two small spots on the pharynx above the left tonsil. On the second day the membrane had spread considerably, covering both tonsils and uvula. In the afternoon a rash appeared, and the following day there was a bright scarlet, macular eruption.

A bacteriological examination on the day of entrance showed a growth of streptococci; no bacilli of diphtheria. On the sixth day the membrane still covered both tonsils and the uvula; on the tenth day the throat was practically clear.

Complications. On the eighth day pneumonia developed in the left lower back; four days later in the right lower back, and the next day, which preceded death, in the left upper front.

Result. Death on fifteenth day from pneumonia. On sixth day general condition septic with rapid, feeble pulse.

CASE XVIII. A girl, eight years of age.

Time. No history. On entrance both tonsils, pillars of the pharynx and posterior pharyngeal wall covered with thick gray membrane. Foul, purulent discharge from the nose.

Rash. Bright scarlet rash.

Complications. Râles throughout the chest.

Result. Death on day of entrance. There was a marked septic condition on entrance. Pulse very feeble and so rapid that it could not be accurately counted.

Anatomical diagnosis from autopsy by Dr. Councilman: Abscess and ulceration in pharynx; beginning croupous pneumonia; acute nephritis; acute splenic tumor; fatty degeneration of heart, liver and kidneys; general lymphatic hyperplasia; septicæmia from streptococcus infection.

CASE XIX. A girl of twenty-one months.

Time. Child had been sick four days. Membrane on tonsil, uvula and pharynx; foul discharge from the nose.

Rash. Dull red eruption on abdomen and thigh which spread rapidly.

Complications. None.

Result. Died on second day. Some retraction of thorax and voice hoarse to slight extent. Marked septic condition.

CASE XX. A girl, eighteen months old.

Time. On entrance a moderate macular eruption. Four days later a patch of membrane developed on the left tonsil and uvula; foul nasal discharge. In three days throat more clear. Rash became bright.

Complications. On the eighth day complete consolidation in the lower part of the left back, and death on second day with a gradually increasing dyspnœa. Septic condition.

RESUME OF TWENTY CASES COMPLICATED WITH MEMBRANE IN THE THROAT.

Age.	Cases.
Under 3 years	7
6 to 10 years	7
13 to 15 "	3
20 to 24 "	3

Time the membrane appeared, or was observed.

	Cases.
2d day of disease	2
3d " "	7
4th " "	1
6th " "	1
1 day before rash	1
2 days before rash	1
3 days before rash	1
Time not noted	6

In the last six cases it may be considered that in five the membrane appeared early in the disease as the following record is made as to the skin.

	Cases.
Intense rash	3
Moderate rash	1
Faint rash	1
Desquamation	1

Seat and Extent of the membrane.

	Cases.
Both tonsils, uvula and pharynx	4
Both tonsils and pillars of pharynx	2
Tonsils and uvula	3
One tonsil and pillar of pharynx	3
Both tonsils	2
One tonsil	2
Whole pharynx and nose	5

Duration of membrane in 6 cases where noted.

Average	6 days.
Longest	10 days.
Shortest	4 days.

Character of the eruption.

	Cases.
Faint, slight or moderate	9
Marked or intense	9
Fading	1
Desquamative	1

Desquamation completed, of 11 cases which recovered.

Average	54 1-2 days.
Longest	70 days.
Shortest	37 days.

Complications.

	Cases.
Slight albuminuria and casts in 4th week	2
Acute nephritis	2
Pneumonia	6
Otitis media purulenta	3
Parietal disease of the heart	1

Mortality, 9 cases.

	Cases.
Foul nasal discharge	7
Acute nephritis	1
Pneumonia	2

Marked Septicæmia, 8 cases, of which only 1 recovered.

The fatal cases were all markedly septic in general appearance from the first except one, and he died of acute nephritis with uræmia in the fourth week, long after the entire disappearance of the membrane, and apparently well-developed convalescence.

Until by the bacteriological investigations of the last few years the question was definitely settled that the bacillus of diphtheria was not found in the membranous deposit on the throat of scarlet fever, great difference of opinion existed as to whether this form of scarlet fever was to be considered as a mixed infection of scarlet fever and diphtheria. Henoch has always been the most prominent advocate of the theory that the membrane was but a local manifestation of the scarlet fever poison. An observation of the clinical phenomena presented by my cases gives a good example of the essential factors on which such an opinion is based.

A deposit of membrane on the tonsils or pharynx is by no means a rare complication. In most cases this membrane shows but little tendency to spread, and especially does not invade the larynx and trachea. The existence of this membrane, with the exception of the intensely septic cases, does not exert any material effect upon the course or prognosis of the disease. Paralyses are not observed. Eleven of my cases remained in the hospital an average of fifty-four days, and paralysis was not noted in a single case. The mortality of my cases was large, nine out of twenty cases, but a closer inspection of the cases shows that in seven there was a foul nasal secretion; the secretion was abundant, sero-purulent, somewhat bloody and excessively irritating as shown by the abundant excoriation about the edges of the nostrils; of seven such cases only one recovered. The other eleven cases in which the membrane in six was widely spread over the tonsils and uvula or pillars of the pharynx, showed no evidence of a septic condition, and the scarlet fever ran the usual course of a mild disease without complications. Otitis media was noted only in the fatal cases.

There is no marked anatomical difference between the pathological lesions as observed in diphtheria and the membranous deposit seen in scarlet fever; in special cases there may be no difference, and at best no factor is of sufficient importance or occurs with sufficient regularity to make a differential diagnosis possible. In the membrane of scarlet fever, the deposit is less firm, it tends to be rather pultaceous and cannot be stripped off in large pieces or strips as in diphtheria. Secondly, destruction of tissue by ulcerative or suppurative processes are more common in scarlet fever than in diphtheria.

In Loeffler's first article on the bacillus of diphtheria he describes the organisms found in five cases of membranous inflammation complicating scarlet fever; in four the bacillus of diphtheria was not found; it was present in the fifth case, but this was one in which the membrane appeared on the eighteenth day and invaded the larynx. Since this work of Loeffler many have sought for the diphtheria bacillus in the membrane of scarlet fever, but in vain. In almost all cases a streptococcus is found, which most observers describe as identical with or very similar to the streptococcus of erysipelas.

Booker has recently published [2] a report of the examination of pseudo-diphtheritic angina in scarlet-fever. In none of the cases where there was membrane did he find the Loeffler bacillus. In all he obtained a streptococcus which differed from the streptococcus of erysipelas essentially in that its vitality in culture media was short. In one of Booker's cases (Case 3) there was a membranous deposit on the tonsils on the second day of the disease and two days before the eruption of the scarlatinal rash. The organism found was similar to those found in the other cases. This case is comparable to two of mine, namely, Nos. 5 and 14, in which the membrane preceded the rash two and three days respectively.

In my cases bacteriological examination was made in four instances. In two I made cultures from the throat during life and in two Dr. Councilman made cultures from the throat and internal organs post-mortem. In the first case (No. 15) there was a marked septic condition, a foul nasal discharge, and the whole posterior pharyngeal region was filled with a soft pultaceous membrane. I found streptococci in the cultures but no bacilli of diphtheria.

In the second case there was a membrane on one tonsil and no rash. The result was the same as in

[2] Bulletin Johns Hopkins Hospital for October and November, 1892.

Case No. 1. In this case the rash developed in twenty-four hours. He gave a history of a sickness of three days, the chief symptom having been sore throat. The membrane was not due to diphtheria, it was not tonsillitis, and I think it fair to assume that in this case, and in Cases Nos. 5 and 14, the scarlet fever poison was the cause of the membrane while the eruption of the rash was deferred to a remarkably late period, the fourth day after the initial symptoms.

In the two cases examined after death by Dr. Councilman pure cultures of streptococci were found in the glands about the neck and in most of the internal organs. It is interesting to note that in one of the cases cultures from the kidney were sterile and no organisms were found in the kidney, though there was an acute nephritis, the acute inflammation having been set up by the toxines produced by the bacteria.

Pneumonia, lobar or lobular, was the immediate cause of death in six of the septic cases. Acute nephritis developed in two of the cases with membrane; one of the cases terminated fatally.

Otitis media was developed in three cases, all of which had a foul nasal discharge. But apparently the existence of the membrane was not an especially predisposing cause of otitis as it developed in six cases of 33 in which there was no membrane.

Pneumonia, lobar or lobular, was present in six cases: the same prevalence of this disease in septic throat cases of scarlet fever is noted by other observers. It is to be considered as the direct result of the general septicæmia which results from the streptococcus infection. In three of the cases the disease was lobar. Only one of these cases recovered, and that was one in which the essential disease was bronchitis though the existence of a few patches of lobular pneumonia seemed to me probable.

In summing up, we can say the presence of membrane in the throat exerted no material effect upon the course of the disease, except in the cases that presented a marked septic condition from the onset, and in these there was an extension of the disease into the naso-pharynx. The deposit of membrane in the throat may precede the eruption of the rash.

The membrane is not due to the bacillus of diphtheria. If the name diphtheria is retained as descriptive of the pathological condition it is practically important to remember that the throat lesion is but a local manifestation of the scarlet fever poison, and does not entail the danger of infecting another individual with the specific disease, diphtheria.

The six cases of otitis media in cases where there was no membrane, occurred in cases which offered no symptoms suggestive of such a serious complication until the onset of the primary fever due to the inflammation of the ear. In all the cases there was a sharp attack of fever, marking the beginning of the attack. In all the cases the discharge ceased before the patients were discharged.

Seven cases were of considerable interest to me in that during convalescence there was a considerable rise of temperature and pulse, without constitutional symptoms, in which repeated careful examination failed to elicit any sufficient cause for the fever. A boy who had an eruptive stage of marked mildness during desquamation, had for two months a temperature of 100° to 101° and frequent examination failed to elicit a single abnormal physical sign.

As two cases had for a varying but short period an irregularity of the action of the heart in rate and rhythm, it seemed to me possible that the mild fever might be due to granular degeneration of the heart. All the cases were kept in bed during the fever so that no strain was brought upon the heart. All the cases with elevated temperature which I speak of finally recovered without untoward symptoms.

NOTE.— Since I wrote this paper an investigation of a considerable number of cases of membranous inflammation of the throat in scarlet fever by Drs. Councilman and Williams, has demonstrated the presence of the Lœffler bacillus. In the light of this work I am wrong in saying that the membranous affection of the throat in scarlet fever is absolutely distinct from the very similar pathological process in diphtheria. — H. J.

A CONSIDERATION OF ERYSIPELAS OCCURRING DURING THE PUERPERIUM.[1]

BY CHARLES W. GALLOUPE, M.D., OF BOSTON.

THE complication of erysipelas with the puerperal state presents many points of medical interest, but perhaps the most important of all, at the present time, is the question of infection. The contagiousness of erysipelas has for many years been hotly argued from the clinical standpoint, but no conclusion could be reached until the development of bacteriology made proofs of another and more definite sort possible. The discovery of specific bacteria in anthrax, gonorrhœa, and other contagious diseases, led to the study of erysipelas by similar methods of inoculation with cultures from known cases. The first important contribution to this subject was a record of experiments on eleven cases, published by Fehleisen in 1883.[2] In each case he found a micrococcus of uniform character, especially abundant in the lymph spaces of the tissues actively affected. This was cultivated successfully and inoculated into the ear of a rabbit, where, in eight cases out of nine, the characteristic signs of erysipelas appeared, and the tissues were found to contain a chain-like coccus to which he gave the name of "streptococcus erysipelatis." Later experiments have proved beyond doubt the bacterial origin of the disease in every instance. Before this fact was demonstrated, and while the evidence was wholly clinical, the non-contagiousness of the disease was claimed by many observers, from the absence in their own experience of instances of transmission and from the failure to trace out in every case the source and method of contagion. This difficulty suggested the theory of an "idiopathic" erysipelas, and also of a special non-contagious form of the disease,[3] while the presence of a gross wound served to distinguish "surgical" from "medical" erysipelas. All forms of the disease are now known, however, to have a single infective cause in the shape of a micrococcus, which enters the system through a wound of the skin or mucous membrane, not necessarily large enough to be visible, perhaps even microscopic, but sufficient to expose the lymph spaces to absorption. In 1884, before this fact was established, D. B. St. John Roosa[4] announced his opinion that erysipelas was always traumatic in its origin. He did not believe that it could be generated in a sound skin, and explained the cases ascribed to cold, to the "trauma-

[4] D. B. St. John Roosa, reported in Medical and Surgical Journal, December, 1884.

tism of a high wind blowing upon the face." In the same year E. L. Partridge,[5] of New York, presented a careful summary of the evidence in these words: "It [erysipelas] is probably never of neurotic origin, nor is it always necessary for it to be preceded by traumatism; there is undoubtedly an idiopathic form in which the poison gains access, in all probability, through the respiratory tract. Of this latter view, however, we have no absolute proof, and the view which insists upon the necessity of an abrasion is therefore entitled to respect."

The fact that erysipelas is now proven to be caused in every case by bacterial infection is sufficient to make its prophylaxis an important matter, and especially in the puerperal patient, presenting, as she does, a wounded surface in the lacerated vaginal wall, and a still more sensitive absorbent area in the uterine cavity with its patent veins and lymph spaces. But the subject assumes a still greater importance when we consider the possibility of erysipelas causing by inoculation a puerperal septicæmia — in other words, the possible identity of erysipelas and certain forms of puerperal fever. In proof of the individuality of the streptococcus erysipelatis, Fehleisen says:[6] "Though somewhat similar organisms are found in the pus of wounds and in pyæmia, the mode of growth of the micrococcus of erysipelas is found to be characteristic." This statement was made after limited experiment, and was disputed on two grounds. First, that some cases of erysipelas failed to show the specific coccus; second, that inoculation of the pure culture from erysipelatous subjects was able to cause, under varying conditions, all the manifestations of septicæmia. The value of experiments of this sort depends largely upon the care and technical skill of the observer, as the failure, in any instance, to discover a micrococcus is not an absolute proof of its absence; while, on the other hand, imperfect sterilization of apparatus might result in the development of other cocci than the pure culture derived from the erysipelatous tissues. A careful series of experiments on the mouse by Fraenkel,[7] in 1889, showed that inoculation of cultures from erysipelas caused, in one case, purulent ophthalmitis, in another peritonitis, and in a third abscess in the skin of the back. The experiments proved, in his mind, the identity of the streptococcus erysipelatis and the streptococcus pyogenes, while the "clinical differences in the disease were due to the mode and locality of the infection, perhaps also to the quantity of the virus and the disposition of the individual." Verneuil and Cado,[8] in 1889, proved by inoculation the identity of acute lymphangitis and erysipelas, and Mosny[9] found on autopsy of a patient who died two days after the onset of an infectious pneumonia, a streptococcus identical with the streptococcus erysipelatis, as proved by inoculation. The characteristic appearance and behavior of Fehleisen's coccus were disputed by Hell,[10] who reached this conclusion after many experiments: "With our known methods [of staining, etc.] can be seen no noticeable difference between pus and erysipelas cocci; they completely agree in morphological and biological aspects as well as in their behavior towards inoculated animals." A further discovery in the investigation of this subject is claimed by Jordan,[11] who states that "besides the true erysipelas streptococcus, not only the streptococcus pyogenes, but also other pus-formers, such as staphylococcus pyogenes, can cause erysipelas." He concludes that "erysipelas is etiologically not a specific disease. It is regularly due to streptococcus pyogenes, rarely to staphylococcus pyogenes. The difference in the action of the pyogenic coccus on the tissues depends upon difference in localization and upon variation in its virulence (increase or diminution). It is of a quantitative sort." This opinion he bases upon the study of two cases of inoculation from facial erysipelas, but that this was not convincing is shown by the comment of a German critic: "So many conclusions on so few cases; a pity they rest on thoughts rather than facts!" An opinion similar to Jordan's was expressed by Atkinson[12] before the American Dermatological Association in 1887 in these terms: "Erysipelas should be considered the expression of the effect of one of a number of specific causes, and, in that sense, should be regarded as a symptomatic inflammation."

However we may view this matter, the repetition of experiments has led to a general acceptance of the interchangeability of erysipelas and the septic inflammations. This is a rational belief to hold, for it is well known from clinical experience that diseases differing widely in their manifestions can be due to one and the same cause, and, in the subject under discussion, experiment has shown that the same inoculation may develop either an erysipelas or a disease of widely different character depending upon, first, the seat of absorption; second, the strength of the virus; and third, the peculiarities of the patient. The influence of the seat of absorption is shown, for example, by its effect on the period of incubation as demonstrated in a series of experiments by Echalier[13] in 1890. He showed "the resemblance of so-called surgical erysipelas to inoculated erysipelas in the short period of incubation [average, thirty hours] while medical, or spontaneous, erysipelas has a much longer period, averaging one week." The effect of variation in the quantity of virus is shown by the experiments of Roger in 1891.[14] A virus, which at first could cause a typical erysipelas, was weakened by re-inoculation, when it served to produce a local abscess only. He states that "the streptococcus experiences no change of growth, but a great diminution of virulence, if one works on the serum of animals who have before suffered erysipelas. After four inoculations the growth of the streptococcus was not stopped, only, instead of erysipelas, a local abscess appeared." The modification of the disease by individual and racial peculiarities is illustrated by a statement of Dr. C. L. Stevens[15] in 1884. He saw in Turkey "many cases of idiopathic erysipelas, asthenic in character, and resembling typhoid fever so common in Oriental cities, though having a more favorable prognosis and a shorter natural history."

If we accept the unity of the bacteria of the several

septic processes, we have one explanation of their varying manifestations in variations in form or quantity of the ptomaïnes produced. A. B. Griffiths[16] has discovered in the urine of erysipelas an alkaloid which he names "erysipeline," but he has not determined if the micrococcus of Fehleisen produces the same when grown in tubes of gelatine. The manner in which these ptomaïnes are formed is not yet determined; they may be an excretion of the micrococcus itself, or they may be a decomposition product of the tissues in which it lives. Each cell of the living body is constantly undergoing a process of death and regeneration, during which a toxic substance is formed which becomes harmful to the body if the quantity is created in excess, or the power of elimination checked. This suggests an explanation of the diverse effects of bacteria, in that different tissues may have the property of producing different alkaloids in the presence of the same bacteria. When general infection results from a local disease, the symptoms are those of the particular alkaloid generated. For instance, some act especially on the heart and circulation, while others act principally on respiration.[17] In the case of erysipelas it is affirmed that "as a rule general infection of streptococci is not commonly found. It can be caused by them, however."[18]

But independently of the proofs of bacteriology, the connection between erysipelas and puerperal fever has long been inferred from their clinical relations. As long ago as 1874 a report by T. C. Minor[19] states that in his investigations "epidemic erysipelas was invariably associated with an outbreak of epidemic puerperal fever, or *vice versa*," and Fiessinger[20] reported in 1889 "an epidemic of puerperal septicæmia of erysipelatous origin." On the other hand, this connection has been strenuously denied, and many instances of noncontagion after exposure quoted in evidence. Kime,[21] in 1888, in a paper entitled "Results of Erysipelas Complicating Pregnancy and Parturition," concludes that there is nothing in common.

The uncertainty of arguing from single cases is evident from the strange coincidences so often seen in the physical world, and in medical matters this is increased by the unconscious bias of the observer. Medical reports are often valueless from the fact that the busy practitioner frequently has neither the time nor the training to make accurate observations, even if unprejudiced in his investigations. It is not sufficient to find *a* cause — it is essential to exclude all other causes to establish the etiology of a case. In some instances an attack of erysipelas is attributed to infection from another case of the same disease, without noting the occurrence of septicæmia before and after in the practice of the reporter, and, *per contra*, a puerperal septicæmia may be traced back to a remote septic origin, while an intervening erysipelas might lead another observer to ascribe it to a different cause.

The number of cases of puerperal erysipelas impartially reported seems very small, and this is due in part to the fact that a typical cutaneous eruption has been considered necessary for the diagnosis. The existence of infection without external signs was claimed by Winckel,[22] in 1886, and the disease called by him "internal puerperal erysipelas"; and in 1890 two cases of acute infectious pneumonia of erysipelatous origin were reported by Mosny, as quoted before.[23]

Winckel reported that he had seen forty-two cases of erysipelas during pregnancy and the puerperal state, six occurring before and thirty-six after delivery. Of the thirty-six puerperal cases, twenty-eight began in the genitalia, two in the breast, and the remaining six in the face and scalp. These cases terminated as follows: In the twenty-eight cases having their origin in the vulva, there were twelve deaths; in the other fourteen there were two deaths. The high death-rate shows the importance of the subject, and the small number of cases recorded leads me to report two cases.

The first is of interest merely as an instance of noncontagion. The patient was a Swede, aged thirty-five, in her fifth pregnancy, all but one of her previous deliveries requiring forceps. I had attended her in October, 1885, for a light attack of facial erysipelas, but did not see her again until the evening of February 13, 1886, when I found her in labor. The case progressed slowly until finally, the pains ceasing entirely, I applied forceps at four o'clock, A. M. of the fourteenth, without ether, and delivered a healthy child of eleven pounds weight, presenting O. L. A. The patient had had a chill the preceding day, and showed a marked erysipelatous blush on the nose at the time of labor. She had high temperature for five days, but no other symptoms, the disease assuming a light form and disappearing in a week. The child was well throughout. In this case there was every opportunity for a conveyance of the contagium to the genital tract, but no general septic infection occurred, and the facial erysipelas ran its course just as in any non-puerperal case.

The second patient was an American, twenty-one years of age, in her first pregnancy. She was of good constitution, of average height and weight, had never had erysipelas, and was perfectly well aside from the ailments incident to pregnancy. Labor began June 1, 1888, and during the forenoon of June 2d she was delivered, without instruments, of a child weighing about eleven pounds. There was a slight, superficial tear of the perineum, exposing perhaps a square inch of raw surface, and not needing a stitch. For two days the case progressed normally, but on the morning of June 4th, forty-eight hours after delivery, I found her with a high temperature and all the discomforts due to fever, but no tenderness or distension of the bowels. Lochia normal. An enema was given and measures adopted to reduce temperature. On a second visit the same day, I found marked redness and swelling of the perineal region, involving the labia on each side, and presenting all the characteristics of cutaneous erysipelas. At the same time the vaginal walls were dry, hot and red as far in as could be readily seen. From this time onward the blush spread, accompanied with great infiltration of the skin and blistering over the nates. At first it spread most rapidly upward, until, on the sixth day of the disease, it had covered the entire abdomen front and back up to the level of the umbilicus, where it ultimately stopped. At the same time it had extended downward on both legs, having by this time reached about the middle of the thighs, and eventually covering the entire surface

of both legs to the tips of the toes. From the commencement of the disease to the final disappearance of the redness and swelling, was a period of twenty-three days, during the first two weeks of which the temperature was almost constantly from 103° to 105°. There were no abdominal symptoms at any time, and no evidence of general septic infection. The child was put to the breast soon after its birth, and throughout the disease obtained a moderate amount of milk, which, however, was not sufficient, so that partial feeding was adopted early. This programme was continued until the infant was five months old, when nursing was discontinued, and during all of this time the child was perfectly well, except for a transient diarrhœa caused by the surreptitious administration of oatmeal. The child died fourteen months later of cholera infantum, but the mother has remained perfectly well to this day, having passed through a second pregnancy a year ago, without complications.

This patient presented a typical surgical erysipelas, starting in the perineal wound, forty-eight hours after delivery. According to the experiments of Echalier, quoted above, the period of incubation of inoculated erysipelas presents an average of thirty hours, and, as the disease appeared in this case forty-eight hours after the formation of a wound, it is easily explained by direct inoculation. The patient was not catheterized, and my hands had not come in contact with her, except at the time of delivery; so that, if the poison was introduced by the hand of the accoucheur, the incubation period was exceptionally long. To discover, if possible, a source of contagion from a previous case of erysipelas or puerperal fever, I have examined my records for the preceding month, and find that on May 6th I attended a patient through an exceptionally easy confinement, who died May 10th of the most violent form of acute septicæmia — the only fatal case I ever had. From that date up to June 2d I had attended two obstetric cases, a case of fresh scalp wounds, and several cases of boils, bubo, etc., presenting suppurating surfaces, in none of which did any sign of erysipelas or septicæmia appear. During the balance of June, and while attending this case, I had five obstetric cases, two of them instrumental, and two miscarriages, in none of which did any bad symptom occur. One case of erysipelas did occur in a patient with a wound of the nose, who came under my care June 22d, the blush appearing at the wound June 28th, thence spreading over the face, not invading the scalp and disappearing in six days.

In considering the puerperal case we are impressed, in the first place, with the fact that the disease was exceptionally severe, both in extent and acuteness. A report by Manfredi and Traversa[24] emphasizes the fact that "the gravest forms of erysipelas are not those which last the longest with circumscribed areas, but those which present a large surface of invasion, as in traumatic erysipelas." In spite of the acuteness of the disease and the favorable opportunities for absorption, the case progressed exactly as if in a non-puerperal patient. A greater interest attaches to the possible source of infection. Inoculated erysipelas presents a short period of incubation, and, as a rule, shorter in the more violent cases, so that we might assume that the seed was planted about twenty-four hours after delivery. In that case it was probably derived, not from the physician, but from the unscientific handling of the nurse, who had used, I afterwards learned, some soiled cloths to bind upon the patient. Doyen, of Rheims,[25] who maintains the unity of the three streptococci of pus, erysipelas, and puerperal fever, says: "To-day the development of puerperal septicæmia can be put to the account of imprudence or negligence"; and certainly there were abundant opportunities for infection, for in 1888 there was not the scientific use of antiseptics in midwifery that obtains to-day. The occurrence of an extremely violent case of puerperal septicæmia, followed in twenty-three days by an equally violent and exceptional erysipelas suggests a possible connection between the two. The occurrence of nine cases of childbirth and miscarriage during the interval between the two cases and during the progress of the erysipelas, some of them involving extensive digital exploration of the uterus, but resulting in no infection, is evidence of negative value only.

A study of the literature of this subject impresses one with the necessity for, *first*, fuller reports of cases, with special reference to the existence of any septic disease in the practice of the observer at the same time; *second*, further experiment on the duration of the vitality of the micrococcus when conveyed by hands, instruments and clothing; *third*, confirmation of either the specific nature of the streptococcus erysipelatis, or of its identity with the micrococcus of other septic diseases. Clinical as well as bacteriological evidence is needed to establish the practical point of defining the duties of the physician in the way of disinfection, or absolute avoidance of obstetric cases while attending septic patients. Laboratory work is necessarily confined to a few men, but every practitioner can report accurately his cases, and so aid in the solution of this most urgent and important point of practice.

Clinical Department.

A CASE OF ACUTE SEPTICÆMIA.

BY F. B. HARRINGTON, M.D.

The death of Dr. Charles Pratt Strong is so striking an illustration of the dangers to which physicians are subjected in the course of their professional work, that it seems desirable to make a clinical report of this case. Dr. Strong died of acute septicæmia six days after operating upon a patient with septic peritonitis, probably of appendicular origin. The nature of the disease was not determined until after the death of the patient. The point of entrance of the septic poison is not known, as no wound was discovered anywhere upon the body. The circumstantial evidence is so strong that there can be no doubt that the disease resulted from the operation, notwithstanding all the usual precautions were taken.

On the day following the operation Dr. Strong performed a hard day's work. He mentioned in the afternoon that the left arm felt somewhat sore, but he did not speak of it again in the evening. He had a somewhat restless night, and decided on the following day not to go out to his work. I saw him then for the first time. He complained of some pain in the left pectoral muscle, left shoulder and elbow. The temperature was normal and the pulse 80. There was a loss of appetite and some nausea. In the evening the

temperature was 100° and the pulse 90. The patient was drowsy through the day, and slept a good deal. There was a trace of albumen in the urine.

On the following morning the temperature was 102° and the pulse was 90. There was some sweating. In the evening the temperature rose to 103° and the pulse to 98. The urine contained a large amount of albumen. The patient still complained of pains in the left arm and back. There was a disinclination to take food. A moderate amount, however, both of food and stimulants, was given.

On the following morning the temperature remained at 103° and the pulse at 98. There was still much inclination to sleep. In the afternoon there was complaint of pain in the right knee and right thigh just above the knee. The temperature remained at 103° and the pulse rose to 108. During the night there was considerable pain in the right knee and thigh.

In the morning there was found to be some fluid in the right knee-joint, and swelling of the lower part of the right thigh. A ham-splint was put on, and the leg suspended. An examination of the urine showed a large trace of albumen, hyaline, granular and fatty casts, but no blood. The temperature had fallen to 101°, while the pulse remained at 108. The patient had been perfectly clear in his mind, and fairly comfortable. In the evening the temperature had dropped to 100°, but the pulse had risen to 120, and was of bad character. The sweating became profuse. The following night was a comfortable one.

In the morning the pulse had risen to 128 and the temperature to 101.8°. During the night the thigh had swollen considerably. The heart's action was feeble, and there was a duskiness about the skin. The respiration, which had remained normal during the entire sickness, rose rapidly during the morning to 50 per minute. On examination, bronchial breathing was detected over the upper lobe of the right lung. The patient sank rapidly and died in the evening, this being the fifth day of his sickness. The thigh in a few hours became dark and greatly swollen, and was covered with bullæ.

The symptoms up to the last twenty-four hours had suggested an attack of *la grippe*, with the usual amount of acute irritation of the kidneys. The condition of the right knee had suggested an acute inflammatory rheumatism. The marked changes in the thigh did not appear until the last few hours. The treatment had been supporting and stimulating. No depressants had been used. The amount of pain was not great, so that opiates were not needed. The patient did not associate his illness with the operation, which was its probable cause. It was subsequently found, on investigation, that, at the close of the operation, Dr. Strong had pricked one of the fingers of the left hand with a needle which was being used in closing the incision.

Several months earlier Dr. Strong had suffered from a synovitis of the left knee, but there had been complete recovery; and no connection could be traced between this and the subsequent illness. There was no evidence of a chronic nephritis.

AUTOPSY.

The preliminary bacteriological examination and autopsy were made by Drs. Councilman and Whitney about twelve hours after death, and the bacteriological cultivations were made by Dr. Stone.

There was lividity of the dependent parts of the body, and the course of the cutaneous veins was marked by dark, dirty bluish-black lines with illy-defined edges. The right thigh above the knee was swollen, dark and discolored, with numerous bullæ containing a dirty-red serum. The lungs contained a large amount of frothy, reddish fluid, but there was no evident consolidation. The muscular substance of the heart and the parenchyma of the liver and kidney were very pale and opaque. The spleen was swollen, pale, and very soft. The other organs presented nothing remarkable. The muscles of the external aspect of the right thigh were dry, infiltrated with blood coloring matter, but there was no evident pus.

Cover-glass preparations gave the character of the bacteria as micrococci, chiefly in long chains (streptococci). Cultures were made from the heart's blood, the liver, kidney, spleen and subcutaneous tissue of the thigh. From all of these there was obtained a pure culture of streptococci. These grew in long chains in bouillon and on agar. In the former they made the fluid cloudy for twenty-four hours and then settled as a white precipitate. In gelatine they grew along the needle track in small isolated colonies. They grew also in milk, but did not coagulate it. On blood serum the bacteria formed small white colonies, at first almost like drops of water on the surface. They developed rapidly in the thermostat at 37° C., more slowly at the ordinary temperature of the room.

The sections of the muscles of the thigh showed that all the intermuscular spaces were distended by a mass of bacteria, there was no infiltration of leucocytes into the tissues, though the blood-vessels seemed to contain an unusually large number of white blood-corpuscles. In sections of the kidney the bacteria were demonstrated with considerable difficulty, in spite of the fact that the amount of kidney substance that one could pick up with a small wire loop gave over one hundred colonies when planted. When found, the cocci were in the intercellular spaces. Neither in the kidney nor in the muscular tissue was there any suggestion of arrangement of the cocci in chains. This was to be seen only when cultivated outside of the body.

The case is one of true septicæmia following a local streptococcus affection, the original point of infection not being evident.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

EIGHTH ANNUAL MEETING, AT WASHINGTON, D. C., MAY 30, 31 AND JUNE 1, 1893.

(Continued from No. 6, p. 146.)

ON THE REACTION OF URINE WITH ETHER,

by DR. ANDREW H. SMITH, New York.

Ether, when very thoroughly agitated with normal urine, gives rise, in most specimens, to the separation of a gelatinous opalescent substance, which may be so dense as to permit the test tube to be reversed without losing its contents. The urine may or may not be acid. Certain other specimens of normal urine will not yield this result unless an acid be added. These specimens may or may not have been acid originally.

A third very small class of specimens of normal

urine will not yield the reaction even on the addition of acid. The substance thus obtained responds to the tests for protein. It is obtained after all mucus has been removed from the urine. It therefore may be considered an albuminoid substance. It seems to be most abundant in the urine of persons having a vigorous appetite and a good digestion. It is scanty or absent when the subject is on restricted diet, or when digestion is feeble; also in the case of young children. The inference is, therefore, that it represents an excess of nutritive proteids taken into the blood and thrown out by the kidneys. It is found in albuminuria after the albumen has been removed from the urine by boiling. It is not found in the washings of albumen thus removed; but if an acid be added to the albumen on the filter, the washings at once give the reaction with ether.

It is possible that some of the cases in which anuria follows prolonged etherization, may be explained by the formation of this gelatinous substance in the tubercles of the kidneys, thus mechanically obstructing the excretion of the urine.

PROBABLE ORIGIN AND EARLY SYMPTOMS OF CERTAIN CHRONIC DISEASES OF THE KIDNEYS,

by CHARLES S. BOND, Richmond, Ind.

Chronic diseases of the kidney with definitely known origin, such as diphtheria, scarlet fever, pregnancy, etc., were not considered in the paper. It was the author's endeavor to ascertain the ultimate cause or causes of those chronic changes found under the ambiguous head of chronic Bright's disease.

The diffuse character of the lesions in the different tissues of the kidney, as seen post mortem, lead us to the view that the irritant or irritants producing these lesions are presented to these various tissues in more or less constant quantities through the blood current. The remote lesions in the arteries of the head, trunk and extremities exemplify the existence of a common origin. In the living subject the wide distribution and general character of the changes are abundantly illustrated by such conditions as hypertrophy of the left ventricle, with or without lesions of the mitral valves, accompanied by hard, resistant pulse, congested mucous membranes, dyspnœa, headache, œdemas, tendency to inflammations of serous membranes, etc. There are many symptoms pointing to the existence of the general lesions long before albumen and casts appear in the urine.

Kidney inflammation is doubtless due to irritants found in the blood. Uric acid may be put in the list as an occasional cause of Bright's disease. Gout is sometimes intimately associated with Bright's disease, and this association proves the potency of uric acid as an irritant. Uræmia is intimately associated with the retention of nitrogenous products. In the early stage of Bright's disease the average daily quantity of nitrogenous products excreted is very much diminished. It is probable that retained nitrogenous products are causative agents in the production of Bright's disease. A great number of chemical compounds may result from the many different foods under varying conditions of digestion in the stomach and bowels. Vicious unions are often formed that not only irritate the walls of the stomach and bowels but also pass into the general circulation and cause more or less continuous irritation to the various tissues of the body. The ptomaines produced in the alimentary canal under certain conditions are probably carried into the blood and act as irritants. Leucomaines formed in the body under some circumstances may primarily or secondarily irritate the excreting organs.

The causes that primarily produce the irritants, secondarily causing that long train of pathological changes so indissolubly associated with Bright's disease, are those agents that disturb the metabolism of the cells of the body, causing them to run down outside of their lines of normal cleavage in their life manifestations, and thereby producing an excess or diminution of products, normal and abnormal, to the blood. In this metamorphosis no doubt many products will yet be found that are not now known to bear any relation to these lesions, and many others are now found in the urine which will be demonstrated to be due to cell disturbances in the otherwise diseased kidney that are abnormal expressions of such cells and that have nothing in common with the original causes of the vessel and kidney lesions.

A STUDY OF ADDISON'S DISEASE AND OF THE ADRENALS,

by W. GILMAN THOMPSON, New York.

The author's research was undertaken with a view of formulating such conclusions in regard to the etiology and symptomatology of Addison's disease as the still limited knowledge of the subject justifies. His personal experience includes three cases with autopsies. To these are added three more from the statistics of the New York and Presbyterian Hospitals. In addition he has collected unreported records of 40 autopsies in which lesions of the adrenals have been noted but without accompanying symptoms of Addison's disease. His conclusions are drawn from the total of 757 cases recorded by many different observers. Autopsies were made in nearly all.

We are obliged to abandon the earlier theory that Addison's disease is absolutely dependent upon adrenal lesion, in view of the fact that many typical cases have lately been observed with well marked bronzing in which the adrenal bodies were entirely normal. Among Lewin's histories, twelve per cent. were of this type. Virchow describes a typical case, with pigmentation, in which the microscopic examination of both the adrenals and sympathetic system presented nothing abnormal. Moreover, it is absolutely established that every variety of adrenal lesion which has ever been found associated with Addison's disease has also occurred without giving rise to any symptoms whatever. A most instructive case is related by Jürgens, where the pressure of a large aneurism caused atrophy and degeneration of the left splanchnic nerve, with typical bronzing and other symptoms of Addison's disease, whereas the adrenals remained normal.

The conclusions which the study of these cases seems to justify are: (1) That Addison's disease is a condition arising from and dependent upon irritation of the abdominal sympathetic nerves through lesions of themselves, their ganglia, or diseased supra-renal capsules. (2) In the great majority of instances (fully eighty per cent.) the disease originates as a secondary or primary tuberculosis of the adrenals, and the sympathetic system is either involved by extension of the pathological process or is functionally disturbed and irritated through the intimate anatomical connection existing between the adrenals and the relatively large number of nerves which they contain. (3) Actual le-

sion of the sympathetic system, which is far more common than heretofore supposed, is not necessary to produce the varied symptomatic phenomena of the disease. Functional disorder through irritation conveyed from the adrenals may sometimes cause all the symptoms, just as in chorea and many of the conditions of aggravated hysteria and other functional nervous disorders, we are often unable to find definite lesions. (4) In a certain proportion of cases (not over twenty per cent.) the adrenals are affected by some other lesions than those of tuberculosis, or else they remain normal (in twelve per cent.) and the sympathetic nerves and ganglia are alone diseased. Dr. Thompson then gave the results of his inoculation and other experiments upon the adrenals, which he has been carrying on at the Loomis Laboratory in the past four months.

DR. WELCH, of Baltimore, did not think it possible to draw any other conclusion than had been drawn by Dr. Thompson from his record of cases. He had seen six cases of Addison's disease, all associated with the characteristic tuberculous lesion of the adrenals; and in two of these tubercle bacilli were found, but only after a long search. In these cases the tuberculous lesions had an unusual localization. In one case there was tubercular deposit in the bodies of nearly all of the vertebræ. In another case there were tuberculous lesions in the mesenteric glands and in the genital tract, but nowhere else in the body. Tuberculous lesions associated with Addison's disease are often peculiar in localization. A few months ago a negro came to autopsy at the Johns Hopkins Hospital, and tuberculous disease of both of his adrenals was found. There had been no suspicion of the existence of Addison's disease. The mucous membranes were carefully examined, and abundant dark pigmentation of the mucous membrane of the gums and of the side and back of the tongue was found. The mucous membrane of the gums and of the tongue of the negro was very often pigmented in health, much more frequently than in white people. It was an interesting question as to how a diagnosis was to be made in the negro.

DR. J. T. WHITTAKER, of Cincinnati, had seen two cases of Addison's disease in the past five years, both of which had shown caseous masses in the adrenals, and one evidence of tuberculosis elsewhere. The diagnosis was established by the digestive and nervous symptoms and discoloration of the skin. The discoloration of the skin occurs, not as an abnormal deposit, but as a physiological plus, and over-accumulation of pigment in places where pigment usually occurs, as in the linea alba, nipples, scrotum and axillary region. He was surprised to learn that in so large a proportion of cases the pigmentation was not due to disease of the adrenals. Brown-Séquard's theory, recently revived, is that it is the function of the supra-renal capsules to remove the pigment from the body, and disease of these supra-renal glands destroys this power and hence the pigment accumulates. It was a comfort to believe that the disease was caused by tuberculosis; for if it were a pure tuberculosis, it might be amenable to some relief.

DR. THOMPSON desired to emphasize the interest that attaches to careful examination of the abdominal sympathetic nerves and ganglia in cases of Addison's disease, and urged those who had opportunities to make pathological examinations not to overlook this point.

TWO CASES OF CYSTIN CALCULUS,

by JAMES TYSON, M.D.

CASE I was a young man of twenty-three years, who first consulted Dr. Tyson in September, 1888. A few days previous had had severe pain in the left flank. Examination of the urine showed the presence of a copious flocculent sediment composed entirely of tablets of cystin. He has had pains in the left flank at intervals ever since, and has passed numerous small calculi, all composed of pure cystin. Repeated examinations of the urine have always shown the presence of cystin. Patient has been upon aromatic spirits of ammonia and citrate of potash; but even while the urine gave an alkaline reaction, cystin was found to be present. The calculi passed most recently have been perfectly smooth, as contrasted with the former ones which were rough, and look as though they had been reduced in size by the action of some solvent substance.

CASE II was a practising physician, aged forty-five, who came under observation in January, 1879. At eight years of age he was lithotomized and a calculus of pure cystin removed. He continued to pass cystin daily through life. Had had numerous attacks of nephritic colic. He died March 6, 1879. A calculus was found in the left ureter just ready to pass into the bladder. It was large as a pea and roughly granular. Behind the calculus and outside of the ureter was a collection of pus dipping down into the pelvis. A single large calculus was found in the gall-bladder, occupying its entire extent. One kidney was much reduced in size, but both were reported as normal.

DR. WHITTAKER asked Dr. Tyson concerning the origin of cystin.

DR. TYSON replied that it was not known.

DR. WHITTAKER called attention to some very fine observations by Brieger in regard to cystin. Brieger derives it as a ptomaine from the alimentary canal, and finds it always in combination with diamine. He assumes it to be found only in connection with infectious diseases. In Dr. Tyson's cases the occurrence of cystin in the urine is a life-long condition; and that is, of course, incompatible with the view that it occurs only in the course of any ordinary infectious disease.

(To be continued.)

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

J. T. BOWEN, M.D., SECRETARY.

REGULAR meeting, Monday, April 24, 1893, the President, DR. C. F. FOLSOM, in the chair.

DR. H. JACKSON read a paper on

COMPLICATIONS OF SCARLET FEVER AS OBSERVED IN FIFTY CASES.[1]

DR. F. H. WILLIAMS: I am very much interested in this subject, but I find myself a little embarrassed because I expect to read a paper which will cover part of the same ground, so that there will hardly be time for me to say all that I would like to on the subject under discussion. As regards the eruption and the membrane in the throat, as a rule, I think the eruption and the throat symptoms will be found together. Sometimes the signs in the throat will come first. Of

[1] See page 162 of the Journal.

course, as the cases come into the hospital, it is hard to know how long they have had the throat symptoms. I have here a list of between thirty and forty cases with throat symptoms; and among them there are three where the eruption came on from four to seven days after the throat symptoms, but that seems to be unusual.

As to the question of whether the throat symptoms influence the prognosis in any way, if I understand Dr. Jackson rightly, he thinks that the cases with severe throat symptoms have about the same mortality as the ordinary cases of scarlet fever. This was not the case in the patients whom I have followed. To my mind the membrane in the throat in scarlet fever makes the prognosis very much worse. I think it is one of the most serious signs that one finds in a case of scarlet fever. There are few things I think of in the early stages of scarlet fever that would incline one to give so bad a prognosis.

As regards the symptoms in the ear, I rather expected, in looking over a number of cases, that one would find otitis media where the throat symptoms were very severe; but in two hundred cases there does not seem to be a marked difference between those with severe throats in these cases and the ordinary cases of scarlet fever, that is, I found about as large a percentage of patients who suffered from trouble in the ear in one set of cases as in the other, but I think it would take a large number of cases to determine a point like this. It seems to me that scarlet fever is a disease in which one needs to have a large series of cases in order to get any statistics. For example, Murchison and others have made some observations about scarlet fever, and find the mortality from three per cent. to ten per cent., or fifteen per cent. to twenty per cent., or even to thirty-four per cent., in different epidemics; also in different seasons of the year the mortality varies very markedly, and I think that during certain seasons of the year one would be more apt to find cases of scarlet fever having membrane in the throat than at other seasons.

Dr. Ayer: I feel that papers like Dr. Jackson's are of the greatest clinical value. I remember seven or eight years ago to have collected a series of cases. There were ten, if I remember rightly, of the twenty-three where the membrane was the most important of all the symptoms; and in one the membrane appeared upon the throat before the rash appeared upon the skin. It has always seemed to me that the throat symptoms were of the greatest possible importance in the prognosis of a case. Most all of the fatal cases I have seen have died with severe anginous symptoms. Those cases used to be called cases of scarlet fever with diphtheritic throat. I think the explanation Dr. Jackson has given is the correct one.

Dr. Jackson, replying to a question by Dr. Cobb, stated that post-nasal examination had not been made, as all the cases were too young and too sick to make such examination possible. Diuretics he had not given as a routine practice, but patients were kept in bed until the abundant desquamation had ceased. They were kept on milk diet during active desquamation. In regard to the prognosis, about eight of the eleven fatal cases had serious throat lesion, but those cases presented a wide-spread membrane, with extension into the nose from the beginning. It seemed to be a furious process from the beginning. He should regard membrane in the throat as a serious complication, but should feel that a limited membrane on a part of the pharynx was not of such serious import. The cases that did badly looked very sick from the very beginning. Any one at a glance could tell that they were in an extremely low septic condition, and of those cases only one got well. The treatment of all was the same.

Dr. Councilman: I should like to ask what clinicians generally think about the nephritis, if they think there is any probability that it may be due to an accidental infection, to a secondary infection from the throat or the lungs in cases of scarlet fever, or whether they regard it as essentially a part of the scarlet fever process and not coming from the mixed infection.

Dr. Jackson: I should think that was rather a question for the pathologist than the clinician. In my student days we were taught that cold was the essential factor, that great care must be taken against cold to prevent nephritis. It seems to me now such views must be thrown out, and the nephritis must be considered as a septic nephritis — I mean as an infective process, not as a part of the scarlet fever. As it developed in the cases in the hospital, there was absolutely no apparent cause. All the cases were treated alike. All were kept in bed for a varying length of time until the active desquamation had ceased, and all kept on a mild diet. The ward is as free from draughts as a ward can be. The temperature is cool night and day. The average temperature was 67° or 68°, so that in the cases as observed there the nephritis could not be ascribed to any such cause as catching cold or improper diet. But it was not especially prominent in the septic cases. The septic cases which died had an acute nephritis, but that was not a clinically recognized process during life.

Dr. Clark: I should like to ask if Dr. Jackson has any theory as to the connection of the membrane in the throat with the scarlet fever process, whether it is simply a complication.

Dr. Jackson: Certain observers have suggested, that the membrane being due apparently to a streptococcus, that the streptococcus might be the cause of the scarlet fever. These throat cases are considered either as the result of a toxine or as a secondary streptococcus infection. Booker is the only writer, so far as I know, who has made extended observations as to the characteristics of the streptococcus; and in all the streptococci which he cultivated from the throats of scarlet fever patients he found the same characteristic, that they were of very short vitality on nutrient media, thus offering quite a contrast to the ordinary streptococcus.

A Bit of Official Wisdom. — The following paragraph is copied verbatim from a board of health report of a town not a dozen miles from Suffolk County. The lucid advice, as well as the English of this intelligent health official, are both worthy of notice:

"Every person who is confined in a house owing to sickness and contagious diseases, should at all times be thoroughly covered with disinfectants, both externally and internally to insure safety to themselves and to others, as in my mind a spread of the same is caused by carelessness on the part of people who know it all, and cannot be told by persons of experience."

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 17, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

LEGISLATION RELATING TO MEDICAL MATTERS IN MASSACHUSETTS.

THE State legislature of 1893 has not passed many laws of direct interest to practitioners; but a few bearing on medical matters will be of interest, especially to medical men of Massachusetts.[1]

The law providing for the registration of deaths by physicians, in connection with the obtaining of a burial permit by undertakers, has been amended so that in cases of still-born children and those dying immediately after delivery, the same form is required as in other deaths, and a penalty is provided for making false statements. The law now reads as follows: "A physician who has attended a person during his last illness shall, when requested, forthwith furnish for registration, a certificate stating, to the best of his knowledge and belief, the name of the deceased, his age, the disease of which he died, the duration of his last sickness and the date of his decease; and a physician who has attended at the birth of a child dying immediately thereafter, or at the birth of a still-born child, shall, when requested, forthwith furnish for registration, a certificate stating to the best of his knowledge and belief, the fact that such a child died after birth, or was born dead. If a physician neglects or refuses to make a certificate as aforesaid, or makes a false statement therein, he shall be punished by a fine not exceeding fifty dollars."

A law regulating so-called sweat-shops provides that all places used as dwellings in which garments are made, intended for sale, shall be licensed and superintended by the police, or special inspectors, and that in cases of danger from infectious diseases or vermin, the State Board of Health shall take charge and control. Also that all garments made in such places shall bear tags, with the name of the State and town in which they were made.

[1] A similar summary for 1892 will be found on page 95 of the Journal of July 28, 1892.

Local boards of health are required to notify the State Board of the existence in their districts of any disease dangerous to the public health.

A law to abate the smoke nuisance in Boston provides that where bituminous coal is used to make steam in boilers, at least seventy-five per cent. of the smoke must be consumed or prevented from entering the atmosphere.

The State Board of Health is directed to investigate the question of a water-supply for Boston and neighboring towns, and to report in January, 1895.

The same board with the park commissioners shall investigate the sanitary condition of the Charles River Basin up to the Waltham line.

The members of the State Board of Cattle Commissioners are given power to enforce rules for the prevention of disease among animals.

Hereafter plumbers must be licensed, and must pass an examination. The examining boards consist of the chairman of the local board of health and the inspector of buildings. It will be no longer possible for any ignoramus to practise plumbing, but the practice of medicine is still unrestricted.

ANNUAL REPORT OF THE BOSTON CITY HOSPITAL.

THE report shows more than ever before the lack of accommodation for the constantly increasing demands made upon the hospital, but it shows a better outlook for the future; appropriations have been secured which, although insufficient for its needs, have made it possible to plan and begin the construction of new buildings. The trustees, with the assistance of the superintendent, have been for many months at work upon plans for a new hospital for contagious diseases. For the purpose of carrying out this work, $271,000 were placed at the disposal of the trustees, for the construction of new buildings; $24,000 were set apart for the construction of a new ambulance stable, and contracts were made for the buildings constituting the Chester-Park Hospital, costing $203,000. The work has progressed during the winter months as rapidly as the weather would permit. Piles and foundations have been laid for a lodge, administration building, domestic building, and one two-story ward. These buildings will be pushed as rapidly as possible during the coming season. Other buildings and alterations await further appropriation.

During the year which ended February 1, 7,512 patients were admitted, of whom 3,572 were medical, 3,152 surgical, and 788 contagious. The average number in the hospital at one time was 433, and the largest 515. The average number of days' stay was 19.24; 387 patients were treated in the Convalescent Home and 14,485 in the Out-Patient Department. The Contagious Service has been extremely active, a larger number of patients having been admitted than during any previous year. This is the first year during the six years the contagious wards have been oc-

cupied that any patients having a claim have been refused admission for want of room. The creation of the Contagious Service, and the isolation of both physicians, nurses and others who do duty in the contagious wards, which measure was thoroughly insisted upon last year, has been found to work greatly to the advantage of the hospital.

During the year a temporary pathological laboratory has been organized, and with the clinical laboratory formerly in use, good scientific work can now be done. Special investigations have been carried on in the diphtheria and scarlet-fever wards, and all patients admitted with diphtheria or suspected diphtheria have been subjected to the test of the pathological laboratory, to ensure diagnosis.

The report of the trustees on the question of establishing branch hospitals has already been noticed.[1] On the question of gratuitous treatment they say:

"Investigation of the claims of various patients in the ward beds has shown the fact that many patients have very properly declared their reluctance to be supported as charity patients, and when their attention has been called to the matter, have seemed very willing to pay for their own board, and have done so. It is the opinion of the trustees that this system of voluntary payment should be still further extended, and that patients, as far as is justifiable in each case, should pay something for their treatment in a hospital ward. The tendency of the times is to this result in other hospitals, both private and municipal. The contrast between American hospitals and foreign hospitals in this respect is largely in favor of the former. In foreign hospitals, not excepting those of England, the general sentiment among patients is that they ought to be gratuitously provided for, while the tendency among the occupants of American hospitals is a great willingness to pay, due to a feeling of independence, and a dislike of becoming objects of charity. It has been generally recognized that the first charit a person in straitened circumstances is ready and willing to receive is medical charity. The first step is thus taken towards pauperism. As a social problem, the trustees believe that it is their duty, as far as possible, to prevent this first step, and to oppose every tendency to pauperism. They therefore deem it their duty to continue the present system of investigation, and whenever it is not a hardship to contribute, to counsel and encourage patients to be wholly or, at least, partly self-supporting. The trustees also think that patients who are able to pay, should meet the actual cost of their support, $10 a week."

ON THE CONTAGIOUSNESS AND INOCULABILITY OF CANCER.

SIMON DUPLAY and Maurice Cazin have recently published an exhaustive study of the above interesting subject,[1] in which they sum up about all that is known respecting the transmissibility of cancer.

[1] Semaine Médicale, 1893. p. 330.

[1] See Journal of January 5, 1893.

They consider the question of the parasitic nature of cancer as still "without sufficient facts to support it."

In regard to the subject of contagiousness, they affirm that of all the modes of transmission of cancer, there is only one respecting which everybody is agreed, namely, that which consists in what may be called autoinoculability. Numerous cases, of unquestioned authenticity, are on record, where a patient already the subject of cancer, has been inoculated in some sound part of the body with fragments of the same cancer. Cornil reports or rather vouches for two cases of cancer transplanted from one part of the body to another on the same patient,[2] and Hahn has had a similar success in a patient under his care.[3] Roger Williams reports similar cases in the *Lancet*, September 12, 1891.

The case is clearly different when a cancerous fragment is grafted upon some part of the body of a healthy individual or animal, having no predisposition to malignant growths. In the immense majority of cases, no result follows the transplantation. Duplay and Cazin give the particulars of eighteen experiments[4] on healthy animals (dogs and rats), in which the transplantation of cancerous tissue produced nothing but local reactional lesions followed by resorption of the grafted fragments.

Their experiments made to test the direct transmission in the same species now number fifty-four, and they make the declaration that whatever may have been the procedure employed, all their results have been negative whenever they had to do with tumors clearly cancerous. The only positive results which they have obtained concern tumors having no epithelial character, but presenting an evident character of persistence and tendency to indefinite growth; as to the nature of this class of tumors they are not yet ready to pronounce.

These writers conclude that direct transmission must be absolutely exceptional, and they add, what, in fact, is commonly admitted, "that the essential condition of development of malignant neoplasms must consist in a special predisposition, certainly hereditary, which we cannot at present define."

The comparison of cancer to tubercle so often made from the point of view of parasitic origin and contagiousness, is no longer justifiable, for (to quote the words of the writers above mentioned) "when in our laboratories we inoculate guinea pigs or hares with tuberculous products, the inoculation produces its effects with certainty; but when we inoculate cancer in the same conditions, as a general rule we obtain absolutely no result whatever."

The authors conclude that "while nothing at the present time warrants us in believing in the direct contagiousness of cancer, we are none the less convinced of its infectious nature, dependent on a process of which we are still completely ignorant. . . . There does not yet exist any precise notion as to the origin

[2] Semaine Médicale, June 24, 1891.
[3] Berlin Klin. Woch., 1888, p. 413.
[4] Semaine Médicale, 1892, p. 61.

and modes of transmission of malignant neoplasms, and if it be proved that cancer has, in a few rare instances, been transmitted experimentally to animals, it is none the less evident that we have no right to speak of cancerous patients as if they were possible sources of contagion."

MEDICAL NOTES.

THE CARTWRIGHT PRIZE. — The Cartwright Prize of five hundred dollars established by the alumni of the College of Physicians and Surgeons of New York has been awarded to Dr. W. A. Holden, of New York, for an essay entitled, "An Outline of the Embryology of the Eye."

MEDICAL CANDIDATES IN JAPAN. — At the last government examination in Japan for license to practise medicine and surgery four thousand two hundred and seventy candidates presented themselves!

INSUFFICIENT NURSING. — At a recent coroner's inquiry in London, several instances of totally inadequate nursing force were brought to light. A patient having committed suicide by leaping from a window, the nurse testified that she had two wards, containing sixty-three patients, to attend to during the night. It would take her two or three minutes to get from the end of one ward, across the corridor, to the end of the other ward. She was on duty for twelve hours at a time. This experience of an insufficient night staff is said to be not uncommon. In some of the largest and most modern of provincial Poor-law infirmaries one nurse has charge of four wards, situated in separate blocks and containing acute and dying cases.

THE CHOLERA. — During the past week the cholera has increased to a very great extent in Russia. Podolia still continues to furnish the largest figures. there being about five hundred new cases each week, with a hundred deaths. In the other districts there has also been an increase in the number of cases, and several sporadic cases have occurred in St. Petersburg. In Austria, and especially in Roumania, the condition is considered more serious than it was last year. In Naples, the official reports record a daily average of five to ten cases and three or four deaths. Other telegraphic reports, which the government has not succeeded in suppressing, give the daily average of deaths as thirty. In New York there have been two deaths from cholera at quarantine. Both occurred in passengers of the steamer *Karamania*, which left Naples July 22d. Several other cases have occurred, but the patients are doing well. Three patients had died during the passage.

YELLOW FEVER. — On July 22d a vessel arrived at Pensacola from Cuba, with two sailors ill. On the 28th they were removed to the quarantine hospital, as having yellow fever. On August 9th, two deaths from yellow fever occurred, an adult and a child, without any suspicious cases being previously reported. Both cases were in the northern portion of the city, one mile from the water front, and separated about five blocks. It was impossible to trace the source of the fever. A panic at once ensued, and the people began to leave the city in large numbers; and all the cities and towns as far as Mobile and Birmingham declared an absolute quarantine against Pensacola. No new cases have occurred yet.

THE NAVAL LABORATORY. — Under an order from the Navy Department the United States Naval Laboratory at New York is to be known as the United States Naval Laboratory and Department of Instruction. Assistant Surgeons immediately after admission to the Navy are to be ordered to the Naval Laboratory and Department of Instruction, for such study and instruction, under prescribed rules and regulations, as may be necessary to familiarize them with the duties of medical officers afloat and on shore. In addition to the instruction in strictly naval medicine they are to have teaching in sanitary science and bacteriology. The course is to cover at least three months.

NEW ENGLAND.

A NOVEL DEDICATION OF A CREMATORY. — A brick crematory for private use has just been finished at Leominster. It is circular in form, about ten feet in diameter on the inside, has a chimney forty feet high. The building will be dedicated by a clambake, the bivalves to be cooked in the crematory oven.

A CASE OF GROSS CARELESSNESS. — The deaths of two children from scarlet-fever in Woburn last week has led to the disclosure of a bit of criminal carelessness on some one's part. Two weeks ago a barrel containing a feather bed was dumped on a vacant lot. The next day a number of children played upon the bed and scattered the feathers over each other. Within the week five of these children were taken sick with scarlet fever, three of them being children of one family, two of whom have died, while the third is not expected to live. The other two children are recovering, having had the malady only in mild form. After the children were taken sick some one burned the bed.

NEW YORK.

MORTALITY. — The weekly report of Dr. Nagle, Register of Records, shows a very gratifying decrease in the number of deaths in the city during the week ending August 5th. The number reported was 829, a decrease of 255 compared with the preceding week, and 140 less than the average of the corresponding weeks for the past five years. This represents an annual death-rate of only 22.70 per thousand of the estimated population, and is a remarkably good showing for the season of the year.

CHOLERA QUARANTINE AGAINST CANADA. — In view of the introduction of cholera into the port of New York by the steamer *Karamania*, a conference of the heads of the different city departments was held August 6th, at the request of the mayor, in reference to the sanitary condition of the city and the precautions necessary for protection against cholera. Among

the subjects discussed was the danger of the importation of disease through immigrants by way of Canada, and a resolution was passed requesting the City Board of Health to urge the State Board of Health to exert every effort to secure a careful system of inspection and quarantine at the points of entry on the State's northern boundary. At a meeting of the Board held August 9th, a resolution to the above effect was adopted. The members of the Board are confident that everything will be done to prevent cholera from passing quarantine, and the purpose of the resolution is to urge the State Board of Health to co-operate in the most efficient manner with the Marine-Hospital Service to prevent its entrance through the Canadian border.

THE NATIONAL QUARANTINE COMMITTEE of the New York Academy of Medicine has concluded its work in drafting a national quarantine law designed to protect American ports from the invasion of disease. The law which it proposes divides the United States into eleven sanitary districts and provides for a National Bureau of Public Health with fifteen members, eleven of whom shall be appointed by the President, with the consent of the Senate, one to come from each of the sanitary districts, and to be known as the Medical Commission. The other four members are to be ex-officio, the Surgeon-General of the Army, the Surgeon-General of the Navy, the Supervising Surgeon-General of the Marine-Hospital Service, and a law officer detailed by the Attorney-General from the Department of Justice. The powers of the Commission are defined and the law provides that they may, at their discretion, invite representatives of State Boards of Health to confer with them.

Miscellany.

MILK-SUPPLY OF CITIES.

IN an editorial upon the milk-supply of cities the New York *Medical Journal* says:

"It is true that great improvement has been effected during the last ten years in the management of cows, in the care of the milk at the farms, and in transporting it to the city, but much still remains to be done. Certain vital points have until recently been overlooked. In Boston, under the supervision of Dr. Rotch, milk produced at farms under close medical supervision can be obtained. He has established the most complete and perfect laboratory in the world. Physicians, by simply writing a prescription stating the percentage of fat, casein, and sugar desired for any special case, can have it delivered daily in the form of absolutely pure, clean milk, the exact proportions of the various constituents having been determined with mathematical exactness. Such laboratories will no doubt soon be established in other cities, and will prove of incalculable aid in feeding infants and delicate children. In New York a few milk companies are selling a comparatively clean milk obtained from farms where close attention is given to the housing and care of the animals and to the transportation of the milk. In most of these a few important points as regards the personal care of the animals and cleanliness in milking have been overlooked. . . . Bad methods result in part from ignorance and in part from carelessness. A few properly conducted dairies would do much to teach the average dairyman proper methods, while the increase of sales and higher price obtained would stimulate him much more."

GROWING PAINS.

THE old-fashioned growing pains have at last received scientific recognition from a German. They have long been mentioned by English and French writers as representing a certain complexus of symptoms occurring during the period of rapid physical growth. German writers have been very loth to recognize this condition as having any characteristic existence. In this position they were doubtless right, for to a great degree "growing pains" has been a diagnosis of convenience or mental perplexity. The greater number of these cases, which have now been studied by Karewski, of Berlin, will be found, if carefully examined, to be due to certain definite and discoverable causes not connected with the process of growth.

In the first place he points out that, as a rule, the pains are not seated in the bones but about the muscles, and are quite similar to those of slight apyretic attacks of rheumatism. All such cases should be referred to their proper cause.

There are, however, a certain number of cases in which there is a mild increase of temperature and more or less dull aching pain about the long bones. It is found that these occur in children who have been growing tall at an undue rate. Karewski thinks it possible that the active bodily exercise at this period of life has given irritation in some way to the epiphyseal lines of the long bones which naturally results in rapid proliferation and growth. When this condition is too marked, there is a mild inflammatory action, with pain and abnormally rapid growth. Consequently, he concludes that children have pain and fever not because they are growing too fast, but that they are growing too rapidly because they are really ill.

He apparently takes no notice of the frequent onset of these pains shortly before school-time, and their relation to pleasurable or dutiful exertions. In America, certainly, this factor plays some part in the cause of "growing pains."

ERYSIPELAS AND CANCER.

THE experiments which have been in progress for some time at the New York Hospital in reference to the cure of cancer — sarcoma, as well as ordinary carcinoma — have now proved so successful that Dr. W. B. Coley, of that institution, has prepared a report of them which is likely to prove of permanent value to the profession. The discovery of the fact that the accidental inoculation of a cancer patient with erysipelas was followed by marked improvement in the cancerous condition suggested to Dr. W. T. Bull the advisability of inoculating other patients with the erysipelatous virus. Accordingly, a number of cases

were set apart, and experiments were carried out upon them by Dr. Coley, under the direction of Dr. Bull. For the inoculations a pure culture of the streptococcus of erysipelas was used, and it was found that about twenty-five per cent. of the cases of carcinoma were cured, while in those of sarcoma the percentage of cures was as high as 40. In order to prove that the benefit thus noted was not due merely to local reaction, the inoculations were made in some instances at a distance from the cancerous tumor. As a rule, however, the injections were made directly into the tumor, and they were repeated every forty-eight hours. The reaction produced was similar to that of genuine erysipelas, though generally much milder in degree and passing away in from twenty-four to forty-eight hours.

In his report, Dr. Coley arrives at the following conclusions: First, that the curative effect of erysipelas upon malignant tumors is an established fact. Second, the action upon sarcoma is invariably more powerful than upon carcinoma in about the ratio of three to one; third, the treatment of inoperable malignant tumors by repeated inoculations of erysipelas is both practicable and not attended with great risk; fourth, the curative action is systemic, and probably due chiefly to the toxic products of the streptococcus; and, fifth, that the method of inoculation should not be employed indiscriminately until further clinical experiments have proved its limitations.

QUININE BLINDNESS.

AMONG the more serious and distressing effects of quinine upon persons over-susceptible to its administration that of blindness is not uncommon. Its onset may be sudden or gradual and not particularly influenced by the amount of quinine administered. To a physician not remembering this possibility the sudden occurrence of this symptom may be a source of considerable perplexity. So far there have been about sixty cases reported since 1841; and Pischl gives an interesting summary of them in connection with the report of a case of his own: [1]

"The blindness is usually absolute; in some there was only amblyopia of varying degrees. The blindness generally sets in suddenly, 'as though you had turned out the gas;' in many cases, however, vision fails gradually, so that it takes a few days before blindness is total. The duration of total blindness, the absence of all perception of light, varies within wide limits — from a few hours or a day or more to several weeks. In one case it lasted three months. In all cases sight was restored, though slowly, and nearly always imperfectly. Central vision returns first; the color-sense is restored later. In some cases the diminution of the sense of light is permanent. The field of vision, which is extremely contracted, enlarges slowly and probably does not wholly regain its normal extent."

Other symptoms noticed were strabismus and nystagmus. The pupil is generally dilated, irresponsive to light, though reacting somewhat to accommodation. The retinal vessels were diminished in calibre, and the optic discs very pale — a condition quite similar to that found in experiments upon dogs, which is best explained by supposing the effect of the quinine upon the vasomotor centre to result in constriction of the calibre of the vessels, and thrombosis. That the drug has some direct action upon the vessel-walls causing an endovasculitis is not impossible.

Pischl's own case, as fairly typical, is of interest. The patient, a man of forty, had been given some five-grain quinine powders for a malarial attack. After taking three powders at intervals of three hours, he began to have aural symptoms; but continued to take the powders for three doses more. The next morning he woke totally blind. Examination of the eyes gave these results:

"Both eyes, viewed externally, appeared normal. The pupils were motionless to light, but reacted slightly to accommodation. Central vision: R. E., $= \frac{6}{6}$: L. E., $\frac{6}{9}$. With $+$ 5 D. he read $\frac{15}{25}$ and $\frac{60}{130}$, but saw only one word at a time. The field of vision was contracted to five degrees. The ophthalmoscopic examination revealed pale optic discs with ill-defined borders, and blood-vessels about one-third the normal size." Treatment consisted of subcutaneous administration of strychnine and the use of the constant current to the eyes for fifteen minutes daily. A month after treatment was begun the field of vision for white was nearly normal, but the field for colors — blue, red, and green — was still contracted to three degrees. The last examination — about five months after the attack — showed hardly any changes. The field of vision for white was still nearer the normal, and the optic disc was more sharply defined.

[1] Medical News, July 29, 1893.

AN ARCHITECTURAL COMPETITION FOR NURSES.

THE *Hospital*, an English journal devoted to nursing and hospital news, has adopted the suggestion made by Dr. Billings at Chicago, that superintending nurses should make known their ideas upon the proper construction and arrangement of homes for nurses. Accordingly, it offers two prizes — a first prize, of seventy-five dollars (£15), and a second prize of twenty-five dollars (£5) — for the two most satisfactory plans for a nurses' home, for competition among "lady superintendents," matrons or nurses, of the British Empire, the United States or the countries of Europe.

The following details are published: Competitors must send in the proposals in type-written form, which must consist of two parts: (1) A statement setting forth categorically all the rooms and accommodation which are necessary in order to make the proposed nurses' home a model of what such an establishment should be where room is provided for from fifty to one hundred nurses; (2) a second statement and plan prepared in similar form which provides accommodation for from one hundred and fifty to two hundred nurses. Each of these specifications (1) and (2) must be accompanied by plans drawn to uniform scale, and must explain how the proposed home for nurses can be extended, should the growth of the establishment render such a step necessary.

The conditions are as follows:

(1) The competitors must send their names and addresses by November 1, 1893, to Dr. J. S. Billings, U. S. Army, Washington, D. C., and all plans and proposals presented for competition must reach Dr. Billings not later than *January* 1, 1894.

(2) Dr. Billings, Dr. Henry M. Hurd, Superintendent of the Johns Hopkins Hospital, Baltimore, MD.,

and Miss Sophia S. Palmer, Superintendent of the Garfield Hospital, Washington, D. C., are appointed as the judges of the papers and plans submitted in this competition, and their decision will be final. Should the papers and plans submitted demand such a course, the judges reserve the right of withholding any award.

(3) All proposals must be type-written on one side of the paper only, and all plans must be drawn to a uniform scale of one-eighth inch to one foot.

It is proposed to publish an account of the competition with a selection from the competing plans.

TREATMENT OF HEAT-STROKE BY CHLOROFORM.

KOERFER[1] reports the successful treatment of cases of severe heat-stroke by means of chloroform. The terrible exhaustion incident to the severe convulsions of heat-stroke, is certainly no small factor in the fatal effect. Those who have watched cases of heat prostration treated with thorough application of cold baths and cardiac supportives, must have felt the incompleteness of the treatment, in seeing the continuance of the convulsions, even during the bath; and the great exhaustion of the heart following each seizure. As Koerfer points out, the circle is a vicious one; the overheated blood acts as an irritant to the cardiac ganglia and so causes excessive action of the heart's muscle already weakened by the action of heated blood on its fibres. The same hot blood excites the nervous centres, raises the reflex irritability, while the resulting convulsions exhaust the nervous system and still further augment the heat production of the body. Cooling of the body, elimination of heat by baths, is of partial service only, if the over production of heat is allowed to go on. This excessive formation of heat seems due largely to the over irritated nervous centres and it was for this reason that Koerfer treated his cases with chloroform inhalation. The patient, a soldier, had succumbed after a hard day of field practice, and presented a typical picture of severe thermic fever. The convulsions were severe, general and frequent, occurring on the slightest external irritation. There was increasing cyanosis, a very rapid, weak pulse, which failed almost entirely during the convulsion. Respiration was rapid and superficial. The convulsions, though still general, were becoming weaker, and in spite of baths and stimulants the patient was rapidly failing. At this point light chloroform inhalation was tried in the hope of quieting the convulsions. The effect was immediate; after a few breaths the inspirations became deeper, the color improved and the tonic convulsions ceased. The heart's action in particular, was improved, becoming steady, where it had been tumultuous, stronger, slower. At the end of an hour and a quarter the breathing was quiet and deep, the pulse regular at seventy, and the chloroform was withdrawn and a small dose of morphia given subcutaneously. After a two hours' quiet sleep the patient woke conscious and convalescent. The after history of the case was not remarkable.

Another case gave the same happy result. It did not appear that the chloroform anæsthesia was more dangerous in the condition of sunstroke, than at other times, and the application of this remedy is certainly worthy of further trial.

Deaths reported 3,188: under five years of age 1,670; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 947, diarrhœal diseases 736, consumption 276, acute lung diseases 161, diphtheria and croup 76, typhoid fever 41, whooping-cough 33, scarlet fever 19, measles 17, cerebro-spinal meningitis 13, malarial fever 10, erysipelas 2.

From whooping-cough New York 11, Philadelphia 6, Pittsburgh 5, Brooklyn 3, Cincinnati 2, Washington, Cleveland, Milwaukee, Brockton, Haverhill and Chelsea 1 each. From scarlet New York 4, Boston, Pittsburgh and Milwaukee 3 each, Washington 2, Philadelphia, Cincinnati, Cambridge and Woburn 1 each. From measles New York 8, Pittsburgh 4, Philadelphia 3, Milwaukee and Worcester 1 each. From cerebro-spinal meningitis New York 6, Brooklyn, Cleveland and Worcester 2 each,

Somerville 1. From malarial fever Brooklyn and Nashville 3 each, New York 2, Cleveland and Charleston 1 each. From erysipelas New York and Brooklyn 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending July 29th, the death-rate was 22.6. Deaths reported 4,478; acute diseases of the respiratory organs (London) 182, diarrhœa 850, diphtheria 96, whooping-cough 94, measles 87, scarlet fever 69, fever 45, small-pox (London 8, Bradford 4, Bolton and Manchester 1 each) 16.

The death-rates ranged from 11.2 in Derby to 34.1 in Blackburn; Birmingham 25.2, Bradford 22.4, Bristol 14.4, Croydon 20.6, Halifax 15.3, Leeds 22.0, Liverpool 31.5, London 21.0, Manchester 27.8, Nottingham 19.4, Portsmouth 24.9, Sheffield 22.8, Wolverhampton 29.7.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 5, 1893, TO AUGUST 11, 1893.

FIRST-LIEUT. CHARLES E. B. FLAGG, assistant surgeon, will proceed to the Yosemite National Park, California, for duty with Troop I, 4th Cavalry, relieving CAPTAIN LEONARD WOOD, assistant surgeon.

Upon being thus relieved, CAPTAIN WOOD will return to his station, the Presidio of San Francisco, Cal.

Leave of absence for one month, to take effect about August 16, 1893, is granted CAPTAIN HENRY S. T. HARRIS, assistant surgeon, Fort Keogh, Montana.

Leave of absence for one month, to commence about September 5, 1893, is hereby granted to MAJOR J. V. LAUDERDALE, surgeon, U. S. A.

Leave of absence for three months, to take effect on or about September 4, 1893, is granted MAJOR GEORGE W. ADAIR, surgeon, U. S. A.

Leave of absence for one month and fifteen days, to take effect when his services can be spared, is granted FIRST-LIEUT. FRANK R. KEEFER, assistant surgeon.

By direction of the acting Secretary of War, the extension of leave of absence, on account of sickness, granted CAPTAIN MARLBOROUGH C. WYETH, assistant surgeon, is still further extended two months.

CAPTAIN MARCUS E. TAYLOR, assistant surgeon, having been found incapacitated for active service, by an Army Retiring Board, will proceed to his home and report thence by letter to the Adjutant General of the Army.

Leave of absence for one month is granted FIRST-LIEUT. ALFRED E. BRADLEY, assistant surgeon, U. S. A.

Leave of absence for one month, to take effect upon the return from detached service of FIRST-LIEUT. HENRY C. FISHER, assistant surgeon, is granted CAPTAIN EUGENE L. SWIFT, assistant surgeon.

PAN-AMERICAN MEDICAL CONGRESS.

SECTION ON OPHTHALMOLOGY.

The meeting of the Section will be held in the Arlington Hotel in Washington, D. C., September 5, 6, 7 and 8, 1893. The session of September 6th will be devoted to the discussion of the subject of "The Detection and Correction of Astigmatism," with the reading of papers upon this subject. The meeting of September 7th will in like manner be given to a consideration of "The Detection and Correction of Muscular Errors."

JULIAN J. CHISOLM, M.D., *Executive President*, Baltimore, Md.
GEORGE M. GOULD, M.D., *English-speaking Secretary*, Philadelphia, Pa.
J. HARRIS PIERPONT, M.D., *Spanish-speaking Secretary*. Pensacola, Fla.

SECTION ON PEDAGOGY.

The meetings of this Section will be held in Washington, D. C., September 5, 6, 7 and 8, 1893.

Tuesday, September 5th. — At 3 P. M. — The President's Address: "Medical Education in the United States." At 4 P. M. — "The Importance of Physiological Chemistry as a Part of Medical Education." By R. H. Chittenden, Ph.D., Professor of Physiological Chemistry, The Sheffield Scientific School, New Haven, Conn. At 5 P. M. — "The Importance of Bacteriological Study to Medical Students, and the Scope of Instruction." By Harold C. Ernst, Assistant Professor of Bacteriology in the Harvard Medical School, Boston, Mass.

Wednesday, September 6th. — At the close of the General Session, 11 A. M. — "A Demonstration of the Cæsarean Section and the Porro Operations." By Gustav Zinke, M.D., Cincinnati, O. At 3 P. M. — "A Contribution to a Study of Methods of Medical Education in the United States." By Bayard Holmes, M.D., The College of Physicians and Surgeons, Chicago, Ill. At 4 P. M. — "Methods of Teaching Clinical Medicine." By F. C. Shattuck, M.D., Professor of Clinical Medicine in the Harvard Medical School, Boston, Mass.

Thursday, September 7th. — At the close of the General Session, 11 A. M. — "A Demonstration with Colored Crayon, of Methods of Instruction in Anatomy and Surgery." By M. H. Richardson, M.D., Assistant Professor of Anatomy in Harvard University. At 3 P. M. — "The Methods of Medical Education." By Victor Vaughn, M.D., Ann Arbor, Mich. At 4 P. M. — "The Aims and Methods of Medical Education." By W. C. Dabney, M.D., University of Virginia.

Friday, September 8th — At 11 A. M. — "The Relation of Biology to Medical Education." By W. T. Sedgwick, Professor of Biology in the Massachusetts Institute of Technology, Boston, Mass. At 12 A. M. — "A Demonstration of the Physiological Action of the Heart." By J. P. Sawyer, M.D., Cleveland, O.

It is intended to obtain the use of an amphitheatre for demonstrations of special subjects. Any contribution to the programme of the Section, either by paper or discussion, is solicited from those especially interested in the problem of Medical Education.

J. COLLINS WARREN, M.D., *President*, Boston, Mass.
CHARLES L. SCUDDER, M.D., *English-Speaking Secretary*, Boston, Mass.
WM. F. HUTCHINSON, M.D., *Spanish-Speaking Secretary*, Providence, R. I.

RECENT DEATHS.

GEORGE F. BIGELOW, A.B., M.D., M.M.S.S., died in Boston, August 10th, aged seventy-three years. He was one of the founders of the Y. M. C. A. in Boston. During the war he allied himself to a reserve corps of physicians in Boston, devoted to the good of the soldiers, and was present at both battles of Bull Run, of Fredericksburg and the Wilderness.

JAMES A. LATIMER, M.D., M.M.S.S., died at Laconia, N. H., August 11th, aged forty-six years. He was a well-known physician in East Cambridge and for four years prison physician to the Massachusetts State Prison at Charlestown.

SAMUEL E. MUMFORD, M.D., died in Princeton, Ind., July 31st. He was a surgeon during the War of the Rebellion and was at one time President of the Indiana State Medical Society.

FRANKLIN LANE, M.D., died in Orange, N. J., July 24th, aged seventy years. In addition to his medical practice he was for a long time literary editor of the *Baltimore-American*.

BOOKS AND PAMPHLETS RECEIVED.

Prospectus of the London Post-Graduate Course. Fourth Year. Winter term. 1893.

Faradism as an Analgesic in the Loosening of Joint-Adhesions. By Douglas Graham, M.D. Reprint.

Boston University School of Medicine, Twenty-first Annual Announcement and Catalogue. July 1893.

Fifty-third Annual Announcement of the Missouri Medical College, Session of 1893-94, and Catalogue of Session, 1892-93.

Lecture.

SECTARIANISM IN MEDICINE.[1]

BY E. R. CUTLER, M.D., WALTHAM, MASS.

(Concluded from No. 7, page 162.)

THESE hospitals are twenty-six in number, and were opened in the following chronological order:

Hospital.	Location.	Date.
Lowell,	Lowell	1840
St. John's,	Lowell	1867
City,	Worcester	1871
St. Joseph's,	New Bedford	1873
House of Mercy,	Pittsfield	1874
City,	Salem	1874
City,	Springfield	1879
General,	Lawrence	1882
City,	Haverhill	1882
City,	Lynn	1883
North Adams,	North Adams	1883
Anna Jacques,	Newburyport	1884
St. Luke's,	New Bedford	1885
Waltham,	Waltham	1885
Cambridge,	Cambridge	1886
Newton Cottage,	Newton	1886
Fall River,	Fall River	1888
Morton,	Taunton	1889
Clinton,	Clinton	1890
Rufus S. Frost,	Chelsea	1890
Quincy,	Quincy	1890
Somerville,	Somerville	1892
Malden,	Malden	1892
Marlboro',	Marlboro'	1892
Holyoke,	Holyoke	1893
Framingham,	Framingham	1893

Note the rapid increase. In 1840 one, and no other till 1867. From 1870 to 1880, five. From 1880 till 1890, eleven. From 1890 to now, nine. Thus seventeen, or nearly two-thirds of the whole number, have been established in the last ten years. Hospitals are also in process of development in the following places, and doubtless in others unknown to me, namely, Charlestown, Brockton, Beverly, Natick, Gloucester, Fitchburg, Melrose and New Bedford. Of these twenty-six hospitals, fourteen are conducted like the larger metropolitan hospitals; that is, all the work is done by the staff, and no allusion is made to sect or school. No provision is made for other doctors to practise in them, or for patients to have any choice of attendant. All of these hospitals opened previous to ten years ago pursued this plan, but since that time eleven out of the seventeen have modified or totally changed it. What has brought about this change? The question of homœopathic recognition in the by-laws and appointment on the staff has done it. This question has been a vital one in the life of all these recently established hospitals, and will be in the case of every one to be established hereafter. It can no longer be ignored in a single instance. The public has watched the experiments already made, and is well posted. Hence I say, on account of the number and influence of these institutions, the question of professional relations is becoming one of vital concern to us all. The right way to treat it should soon be evolved and universally recognized. If serious mistakes have been made, the fact should be made plain to those who must grapple with the question in the future, that they may avoid them. If any way of settling it can be devised which effects an honorable and permanent compromise between a clamorous public and a resolute profession, it should be urgently recommended by the general medical society or its representatives, the councillors.

I shall try to give you the present status of the experiment. No two of these eleven hospitals have adopted precisely the same details, but for brevity's sake I will generalize and classify as far as possible.

Only two still use the word "allopathic," namely, the Fall River and the North Adams Hospitals. Newton used it first of all, but dropped it in its later reports. The word "regular," as a substitute for it, is used by Quincy and Clinton. The expression "member of the Massachusetts Medical Society" is used in four cases in antithesis to "member Massachusetts Homœopathic Medical Society," and the appointments expressly required to be divided *pro rata* between them. The word "school" appears in the by-laws of all those places which recognize any professional distinctions at all, except Malden, which consistently adheres throughout to the language "fellow of the Massachusetts Medical Society" and "member of the Massachusetts Homœopathic Medical Society." In all of this class, patients are allowed to choose the "school" by which they shall be treated, excepting Malden again, which allows choice of member of one of the above societies, that is, the member on staff duty at the time. In a few of these places other physicians beside those on the staff have the privilege of treating private, paying patients in the hospital by permission of members of the medical boards. The plan pursued in Malden, of distinguishing practitioners simply according to their membership in the two chief medical societies, is ethically unobjectionable, but I think not so good as the one outlined below.

In only one of all these hospitals has the question of medical sects been completely ignored, and still a fair attempt been made to conciliate sectarian opinion by ample and yet honorable concessions. This scheme has been carried out in Waltham, and is as follows:

No allusion whatever is made to distinctions among legally qualified physicians. All alike may introduce either free or paying patients into the hospital, and treat them there. The hospital simply furnishes board, nursing and medicine, and must be paid for the same before the doctor can receive a fee. All patients, free and paying alike, may choose their medical attendant by personal names, not by sectarian title (but, of course, changes are not allowed on frivolous grounds). Patients having no choice are treated by the staff, in all cases gratuitously; but the latter are not precluded from having private paying patients while on duty. Invidious distinctions have thus been entirely ignored, while the doors have been thrown more widely open than in any other general hospital known.

An obvious criticism of this plan is that confusion must arise from having several doctors making their visits at the same time. It cannot be denied that in a large hospital this criticism might have considerable force, and the difficulty could, perhaps, only be met by having different nurses accompany different attendants. I feel confident that it could easily be surmounted by this or some other means; and it would not often arise in such hospitals as are here under discussion. As a matter of fact, it has not yet caused any serious inconvenience in the Waltham Hospital, where from twenty to thirty patients are usually under treatment by five or six different physicians.

It has usually been found that in emergency cases, such as severe accidents, the subjects being often stran-

[1] Delivered before the Middlesex South District Medical Society.

gers, the regular staff attendant has been preferred. But these cases are comparatively few, so that actually only about one-sixth of the whole number of patients is attended by the staff officially. Nearly all cases, even of accident, are brought in by some doctor who has seen the case outside; and he retains it, if so decided between him and the patient.

Of course, this scheme is not satisfactory to the homœopaths, because they wish special recognition; but it is obviously perfectly fair to all, and would be universally acceptable, I believe, if one example of the surrender of principle had not infected the whole State.

The facts above set forth illustrate two distinct methods of dealing with the question herein discussed: (1) The method of explicit recognition of schools or sects in the profession, and an attempt at a *pro rata* representation of the same on governing boards and practising staffs, the latter to have almost or quite exclusive charge of the hospital service. (2) A total ignoring of intra-professional distinctions, with the establishment of such regulations as shall practically secure to each individual in the community the enjoyment of all the benefits of the institution.

I will endeavor fairly to contrast the two methods.

(1) That of expressed recognition.

It has an appearance of great fairness, and thereby secures the favor and pecuniary support, not only of the homœopathic sect, but is equally pleasing to the non-homœopathic layman, who can seldom comprehend the ethical argument or sympathize with our sensitiveness to it. The whole subject is for him cleared of its difficulties when we abandon it. The homœopathic practitioner is satisfied because he secures an official endorsement of his sectarian character. That these considerations have great practical weight is shown by the fact that in the places named they have overcome the objections of the general profession; but, on the other hand, it must be said that this arrangement practically abandons the one essential point in our long contention, namely, that medical sectarianism is professional immorality. On this ground alone can we consistently oppose it, and on this ground we ought forever to stand. The worst feature of the arrangement is that it not only recognizes homœopathic sectarianism, but it in all cases implies, and in some expressly allows, that we, too, constitute a sect or school, namely, the "allopathic" or the "old" or the "regular" school. Now I, for one, indignantly protest against this degradation. Must the enormous majority of medical men assume or accept a partisan appellation because a small minority choose to adopt one? The only title any of us rightfully possesses is "Doctor of Medicine." Anything other than this indicates a self-imposed limitation. It should bind one who adopts it to the strictest exclusiveness in his work, otherwise it has no significance. We ought steadfastly to decline to enter into any relation or discussion which puts the general profession on the same level with a sect. I can but deprecate the humiliation involved in the position of those who accept a diminutive title simply for the convenience and personal benefit of a group of sectaries. For it can in no way be claimed that the good of the public or the institution is directly subserved by the use of these titles. True, certain beneficent institutions seem to be pecuniarily benefited by the unworthy attitude of the doctor; but the public can never be a gainer when it pays its money to debauch the sensitive conscience of a high-minded profession. Already is charlatanism in insidious forms too rife among us, but never has it appealed to us with arguments more specious or more powerful than in this instance. Again, the method of sectarian recognition involves such puerile details as the division of single wards, the assignment of the cases to the separate "schools" by a matron or other unprofessional person incompetent to judge of their needs, and the begging of the whole important question of medical treatment by submitting it to the ignorant patient on his entrance to the hospital.

It virtually pledges the practitioner accepting a position under these conditions beforehand to a certain kind of treatment; for, let it be noted, he does not appear in this arrangement as a private individual, at liberty to use the widest scope of professional judgment, but as a member and representative of a sect. The patient might as properly be given the liberty to dictate his diet on entrance as to choose his medical treatment. The circumstances here are very different from those surrounding a case in private practice. If a patient chooses a so-called homœopathic attendant at home, and the latter applies non-homœopathic treatment, it involves merely the deception of the individual patient who undoubtedly *is* deceived, and also a question in casuistry on the part of the doctor. If he can persuade himself that such conduct is right, that is one thing. But it is quite another when in a public institution to whose service he was chosen in an expressly sectarian character, he is selected by a patient, who quite likely has no personal acquaintance with him or his professional skill, for the direct purpose of securing the kind of treatment indicated by his title. The deception, in case any other than the chosen treatment is used here, is shared by the administration, and the patient is doubly wronged, because in the hospital he practically loses the power to change his attendant if he recognized the fraud. He might, perhaps, remonstrate that if he had supposed his case required surgical or any other than strictly homœopathic treatment, he would have chosen differently, but it would probably avail him little. At any rate, the stultification of the practitioner is evident.

(2) The plan of ignoring all distinctions and reducing the work of the staff to the lowest possible limits, and electing the same by annual ballot of a representative body of trustees.

This plan not only appears to be, but actually is, absolutely fair to all. True, it does not recognize self-imposed titles; but neither does it compel any one to accept titles imposed by others.

It recognizes the legal equality and the professional dignity of all medical men. It provides perfectly for the preferences (and even prejudices) of each possible patient, while refusing the preposterous claim of such to dictate his treatment, which he does when he chooses a "school" instead of an individual. It should make the hospital an object of interest and pride to the whole profession, and prevent the jealousies and rivalries which arise under the system of an indefinite appointment of a staff having exclusive charge of all patients entering. It would tend strongly to break down sectarian distinctions outside its walls, by promoting acquaintance, discussion, comparison. It would secure a united and enthusiastic support of all classes of people, and greatly add to the amount and efficiency of its work and its consequent value to the public and

the profession. It simply prevents the hospital from becoming the tool of sectarian propagandists.

TWO ESSENTIAL DIFFICULTIES IN THE PRESENT SITUATION.

So much for a pretty general review of the evil results of sectarianism from a professional point of view.

Having to a degree cleared up the diagnosis and symptomatology of the case, I proceed without delaying upon clinical history or prognosis, to say that observation and discussion, together with the strong tendency to recovery inherent in so vigorous a body as the medical profession, have already eliminated numerous complications and collateral symptoms which have greatly obscured the situation; and it is now pretty plain that the really essential and intractable features of the malady are two, namely, bigotry and intolerance on the one hand (leading to non-intercourse and even measures of repression, such as debarring or ejecting from societies and hospitals), and, on the other hand, a sophistical defence and disingenuous use of an offensive partisan title.

Let us examine these two radical difficulties.

(1) The conduct of the main body of the profession has been and still is bigoted and intolerant. I believe it to be true that very few non-sectarian physicians know anything worth mentioning about either the theory or practice of the homœopaths. Most of us are not on such a footing with any such individually as to frankly and freely discuss the subject with him. Most of us, again, have little time or inclination to read homœopathic books or journals. Very few of us, I believe, have ever visited a homœopathic hospital. True, we are all more or less familiar with the average homœopathic practitioner, but are inclined to make much of his inconsistencies and his failures, and correspondingly little of his successes, or to ascribe them to his use of other than homœopathic means.

Most physicians have a feeling of bitterness toward these men; and some, even still, call them all either knaves or fools. In the past they have been systematically ostracized; and some have been expelled from societies with which they had been long connected and in which they wished to remain.

Now, to entertain such feeling and use such language, and proceed to such extremes of harsh treatment, while knowing really not very much of the merits of the case, I pronounce bigoted and intolerant to a most reprehensible degree. So long as the above remains true, it is an effectual bar to union.

(2) Offensive partisan titles are still used; and, on the part of the homœopaths, this use is disingenuous and its defence sophistical. The use of distinctive titles by non-sectarian practitioners was never their choice, but they were almost compelled to use some one of them by the voluntary assumption of others by the sectaries. Here was a fatal surrender, as already explained; and the titles accepted or adopted were scarcely less objectionable than that of homœopath. In spite of the difficulty and inconvenience they should have steadfastly refused to accept any title whatever except their legal one of Doctor of Medicine. Look briefly at these terms "allopathic," "regular," "old school."

The expression "allopathic" indicates no accepted principle in medicine, and applies to no class of practitioners.

The impudence of those who would, if they could, force medical men who do not believe in homœopathy as a general principle, and who refuse to place the slightest limitation upon their practice to accept the title "allopath," is colossal. As well might a man who calls himself a Christian, insist that all who do not accept his belief and practice should call themselves heathen, because that word is the proper antithesis to the other. Even if our sectarian friends can say that our practice, as compared with theirs, is allopathic, does it follow that we must adopt the title, in order that they may be aided in setting themselves up as a distinct class before the public?

The word "regular" has been generally accepted by the profession as the least objectionable term, but it is really far less appropriate than "allopath." It is precisely as applicable to homœopaths, if legally prepared to practise medicine, as to any one else. "Old school" is a misnomer of the most ludicrous kind. Modern non-homœopathic therapeutics, so far from being old, are so new that a treatise on them is antiquated in ten years, while Hahnemann's works of sixty or eighty years ago are still the standard gospel of homœopathy. The word "school," which means "the followers of a teacher, or the adherents of a system of doctrine," is likewise wholly inapplicable to the general profession, which long ago abandoned authority and theory as their guides in treatment, and are following as rapidly as the nature of the case will allow in the way blazed before them by scientific investigation. In fact, no expression could more accurately describe two distinctive features of homœopathy than "old school."

Other terms which are frequently used as descriptive of modern therapeutics are "scientific" and "rational"; and if used in a comprehensive sense to include the spirit and aim as well as the details of medical practice, they are correct. But when used distinctively to characterize non-homœopathic medication, they are far too pretentious. Indeed, most, if not all, homœopathic apologists lay claim to the term "scientific," for the reason that, as they say, their system is based on the one natural law of cure. This claim is absurd, for two reasons: (1) It begs the question; for the immense majority of scientific men see no such comprehensive law, but only an occasional, perhaps frequent, coincidence; (2) Their practical success is too small to base any such claim upon. If this law (or fact or rule or guide) is scientific, it must be unvarying and without exception; and while giving full weight to the complicated conditions of the case and to the great imperfection in the present results of homœopathic provings, it appears to me that the fruits of nearly a hundred years are truly disappointing and pitiful.

I have tried a few times to find some item of homœopathic practice which I could test for myself, without resorting to indices and repertories and provings, but with little result. I have tried to observe whether the success of my homœopathic neighbors was so much greater than my own as one would expect if they possessed a guide so greatly superior to my very unsatisfactory one, and I have not thought that it was. I have seen columns of *ex-parte* statistics; but, for reasons well known to you, I have not been convinced by them.

I wrote a few weeks ago to a man well known to some of you, a graduate of Harvard University and of one of the New York schools of medicine, and later an interne in some of the New York hospitals, but

who later embraced homœopathy, and who has been for several years Professor of Materia Medica in the University of Michigan. I put to him this question: "Have you yet found either a recognizable morbid condition or a group of subjective symptoms which you feel reasonably sure you can treat successfully under homœopathic indications which you could not have treated successfully before adopting homœopathy? He replies as follows: "My answer is 'No.' But it has rarely occurred that, since taking up with homœopathy I have preferred to use a drug not selected as homœopathic." Now if *similia* is a scientific law, or even an empirical fact, it certainly is disappointing that my friend, who is familiar with the ordinary practice as well, should not be able to give me a single practical statement by which I could test for myself the value of the doctrine. Now I submit again that here is small basis for the foundation of a sect and assumption of a distinctive title. The word "empirical" is the most correct one to apply to all medical practice — homœopathic included — because all is very largely based on observation and experience; but the word carries an opprobrious significance which is unjust to all.

In fact, these and all other descriptive adjectives should be unconditionally repudiated, and not even allowed for purposes of discussion; and the legal, generic, all-sufficient title of Doctor of Medicine or physician adhered to.

Now we reach the word "homœopathic"; and here we get at the true inwardness of the second obstacle to the unity of the medical profession, and a formidable one it is. It has been discussed with warmth within the homœopathic ranks; but I judge the prevailing sentiment there to be strongly in favor of its continued use, though its gradual disappearance from the signs and cards of individual practitioners indicates the recognition of the fact that its employment there is, to say the least, in bad taste, and is to my mind also an omen of a better day when all shall acknowledge that its use anywhere is unprofessional.

What now are the reasons alleged for the use of the terms "homœopathic," etc.? There is published, in the Transactions of the Homœopathic International Congress of 1891, an address entitled, "The Ethical Basis of the Separate Existence of the Homœopathic School." After acknowledging that the claim that better medication by one school is not a sufficient ethical reason for its separate existence, the author makes two assumptions; first, that the general profession is not "sufficiently emancipated from conscious personality, rancor, jealousy and vindictiveness" to administer upon the ethics of the case — to which I agree; he then assumes that his audience is free from these disqualifications — to which I entirely disagree. He then proceeds to give the usual ridiculous libel upon non-sectarian practice, and contrasts it with homœopathy, to the glorification of the latter. On the basis of this parallel, together with the fact that empirical medicine has never developed any general law of therapeutics, and the assumed comparative unfitness of his opponents to adjudge the question, he rests his argument. The remainder of the article is a high-pitched rhetorical scream, in which homœopaths are urged to an onslaught on the general profession all along the line, with the purpose of its complete subjugation. In the year 1885, Dr. Conrad Wesselhoeft, of Boston, gave a lecture on homœopathy before the Boylston Medical Society of the Harvard Medical School; and in 1886 Dr. V. Y. Bowditch replied in an address before the Massachusetts Homœopathic Society.

As I am not concerning myself with the comparative merits of systems, but, on the contrary, trying to show that such comparisons are not relevant to the question of medical unity, I will not analyze these excellent papers. But in the preface to his lecture (which I advise you all to buy of Otis Clapp & Sons, and read for yourselves) Dr. Wesselhoeft gives the true and only reason for the separate existence of the homœopathic school and the use of the distinctive title, namely, that the distinction may be kept before the public. He reaches the conclusions that (to quote), "it would be a wrong on our part, a gross deception of ourselves and the public if we disavowed or denied our principles, and failed to define our practice by an appropriate term." Again, he says: "After giving up all claims of perfection and infallibility, it by no means follows that a physician accepting the method known as homœopathy must of necessity practise it exclusively. He may do so if he chooses, or he may not apply it always. But, "if a physician adopts any therapeutic method, his colleagues, no less than the public, have a right to know what that method is. Any secrecy or concealment of methods is quackish. Not the publicity, but the concealment of convictions, would be sailing under false colors." He then proceeds to charge the profession with sailing under false colors because they do not openly acknowledge and profess that they practise allopathy.

When one fairly takes in this astounding turn of logic it is liable to produce a state of asphyxia.

When we realize that we are the ones who are quackish and are deceiving the public because we do not openly avow the allopathic principle, according to which we are really practising, we can only hang our diminished heads and plead that we did not know it.

This line of reasoning would not only justify the hypnotist and the electro-therapeutist in announcing their special method of practice, but even require them to do so because they believe in and employ it when they choose. The logical sequence really is that the individual who announces that he "doctors both ways" is the most honorable and consistent of all. The disingenuousness of this position that the homœopath is the really honest man is illustrated by the well-known fact that he seldom tells his patient what medicine he is giving him, even if he is asked to do so, while the physician who writes a prescription, though in Latin, according to a bad custom, cannot effectually conceal his treatment even if he would.

True, it is often best for the patient not to know what medicine he is taking, because he really knows nothing about its action, and his prejudiced or ignorant ideas may be a serious obstacle to a favorable result. But it is equally true that he knows as little about the general system as about the special drug.

If he prefers the homœopathic system on theoretical grounds, his conclusion is a mere instance of the *reductio ad absurdum;* for not even the educated homœopathic physician himself can give any scientific or satisfactory explanation of the doctrine of Similars (see preface to Dr. Conrad Wesselhœft's translation of Hahnemann's "Organon"). If he prefers homœopathy on practical grounds, the fact looms up that no homœopath nowadays claims to adhere strictly to the

system, so that the patient does not know whether he has been treated homœopathically or not. In either case his opinion is absolutely worthless, and to defer to it or appeal to it, as is done in the use of the sectarian title is a thoroughly quackish subterfuge.

It is recognized in all the professions that it is unworthy and shameful for a man to blazon before the public his skill, his specialty, his success, his educational advantages, or even his methods and opinions. The only possible object of assuming a title indicating any of these things is personal emolument. It is advertising, pure and simple.

Furthermore, no amount of specious argument can conceal the dishonesty of varying from a line of practice after publicly and voluntarily adopting a title descriptive of it, without frankly explaining such variation each time to each patient.

Do our homœopathic friends do this? Echo answers.

Now, recognizing these two evils, bigotry and intolerance on the one hand, and a self-justifying sectarianism on the other, how can union ever be brought about? It is evident that it cannot be accomplished by compulsion or repression or by any heroic or revolutionary measure, but rather by the slow and perhaps painful application of what I may call the principles of social physiology or hygiene.

I remember to have read somewhere as follows: "Whatsoever ye would that men should do unto you, do ye even so to them." And, again: "Thou hypocrite! first cast out the beam out of thine own eye, and then shalt thou see clearly to cast out the mote out of thy brother's eye."

In accordance with these rules, let us begin at home, and see what can be done.

REMEDIES.

In the first place, recognizing the perfect right of every doctor to believe and practise whatever commends itself to his judgment, let us expunge from our by-laws the section above referred to.

If any man believes in *similia similibus curantur*, let him believe in it: where is the harm or wrong?

If any man chooses to affiliate with others of like belief in a society for the proving of drugs or the advancement of homœopathic practice let him do so, but do not bar him from medical societies of a general scope. If he can learn more to his advantage in the former than the latter, so much the worse for the latter. Let him freely choose.

If he prefers to send his patients to a so-called homœopathic hospital, or to visit it himself for instruction, let him do it. If the practice there is more successful than elsewhere, it ought to prevail. If not, the way to convince him of the fact is not to call the other party hard names, but let him see and judge for himself.

I deprecate as much as any one the existence of these sectarian schools, societies and hospitals; but deprecation is belated and unavailing. They are here, and here to stay. We must make the best of that. The democratic principle of a fair field and no favor is as much in place here as on the ball ground. It is idle to expect these institutions, which may be called the vested rights of the sect, to renounce their sectarian names, at least at present. I am persuaded, however, that their distinctive features would gradually fade, under the conditions herein proposed, till not enough remained to justify the name, even to their promoters. The chief difference now lies in the item — an important one, to be sure, in their eyes — of drug-therapeutics. That this item must steadily diminish in importance compared with the enormous resources of non-medicinal treatment and with the vast general departments of medical study, such as biology, physiology, psychology, bacteriology, chemistry and hygiene, and their application to the prevention of disease, to education and to all the conditions of human life, seems to me self-evident.

On the other hand, I deny the right of the Massachusetts Medical Society to inquire into the intentions of its proposed members, to exact pledges of them, or to interfere in any way with matters of private judgment, or officially to stigmatize any system of practice. Every one of them ought to employ whatever means he thinks will conduce to the cure of his patient, and should have the fullest liberty to do so. A central board of examiners should be appointed by, and in behalf of the public, without whose certificate no man could practice medicine in the State. This could easily be obtained if the whole profession demanded it. Then all the licentiates of this board should be admitted to the State Society without further test, and these State licenses should have an inter-State value. It would obviate the need of the present examination at the hands of the censors. Even if the present plan is changed, as proposed by the officers of our Society, so as to have a uniform examination, it is a vexatious thing, and keeps large numbers of respectable men outside of the society. The Massachusetts Medical Society should include in its membership every reputable practitioner in the State.

The gross changes in these homœopathic institutions as well as in the Massachusetts Medical Society would doubtless be of slow development, and would be brought about by interstitial and molecular movements represented by the mutual reaction of their individual constituents. Therefore, I urge, in the second place, that sectarian distinctions be entirely ignored in the private relations of medical practitioners, with one very important proviso, namely, that no man should be deemed worthy of fellowship who personally advertises his therapeutics; and I hereby announce my individual purpose to be guided by this principle, within limits set only by circumstance and my private judgment. I am by no means alone in taking this course. It is well known that many specialists in our large cities have practically adopted it. In the New York State Society, largely through the influence of the specialists, the whole code of ethics has been abolished, and consultation is unrestricted, though a minority has an organization of its own in which the code is still accepted. Hobart Amory Hare says in a foot-note on page 19 of his "System of Practical Therapeutics," "The time has, in my opinion, come when the regular physicians should no longer, by refusing to consult with homœopathic practitioners, recognize their separate existence."

Professor Hare advises this course on the ground that there are really no longer any genuine homœopaths, and adduces reasons for the statement. While I agree that there are few if any doctors left who practise a pure and exclusive homœopathy, I prefer to take my stand on the broader ground outlined in this paper, that they have a perfect right to practise, advocate and advance it as much as they can, within the bounds of professional propriety.

In my judgment, free professional intercourse would soon lead to a correct estimate of the value of homœopathic theory and practice, both within and without the profession; and the only insuperable obstacle on the part of its votaries is their public, individual assumption of the extra-legal title.

The law of the survival of the fittest may be fully trusted to differentiate the good and the genuine from the evil and the fraudulent; but the condition of its operation is inexorable, namely, the freest possible opportunity for the two to mingle.

It is not by formal papers that conviction or agreement can be attained, but by colloquial discussion of concrete cases, and the critical watching of effects by interested and vigilant observers. Therefore, I say, throw down the party walls. Let consultation, discussion, comparison, and competition decide differences which many years of exclusion and intolerance have only aggravated and confirmed. Furthermore, let all reputable practitioners be cordially welcomed to membership in local medical clubs and societies.

If our sectarian friends fail to respond to these conciliatory and somewhat costly advances on our part, we shall at least shift from our shoulders to theirs the onus of bigotry and narrowness. Whether they would submit to any process looking to their ultimate extinction as an organized sect, I cannot say. They realize full well that their name is at present a tower of strength as far as securing patronage is concerned, and much more important to them than any peculiarity in their practice. But it is certainly true that obtrusion of the obnoxious title before the public on the private card and sign has largely passed into disuse, in obedience to that sense of professional honor to which this paper is intended as an appeal.

In hospitals let the staff be composed of such men only as are skilled in diagnosis and in surgery sufficiently to meet the emergencies which arise in infectious and traumatic cases, whatever may be their opinion concerning drug-therapeutics; and let the hospital sustain them in their official work, which should, of course, be gratuitous. In all other cases let the hospital assume no legal responsibility, and treat all practitioners alike. Let every patient, at least in the small hospitals, whether he pays or not, if he wishes, choose his medical attendant. Let no mention be made of any sectarian name. Just here our colleagues in various places have missed the vital point. They have compromised with loss of honor, because they have recognized and dignified sectarianism, both in themselves and in the homœopaths.

This plan compromises indeed, but yields no essential point. They recognize the antagonism as irreconcilable, and rest satisfied with mutual toleration. This plan ignores the distinctions and aims at organic union.

In the last International Homœopathic Congress — whose records I earnestly wish each one of you might read, if you wish to get a fair idea of modern homœopathy — the following resolutions were adopted as the sentiment of the Congress:

"*Whereas*, The proceedings, papers and reports of the Fourth Quinquennial International Homœopathic Congress conclusively show that the principles of homœopathy and its practice by educated men and women has obtained a firm footing in every civilized country on the globe; and

"*Whereas*, Notwithstanding the untold obstacles and opposition it has encountered, homœopathy has steadily advanced in professional and public estimation, until now, at the close of nearly a hundred years of incessant and desperate struggle with its foes and the repressive influence of inimical laws, its future permanency and continuous progress are, humanly speaking, assured; therefore,

"*Resolved*, That this International Convention would respectfully suggest to the non-homœopathic portion of the medical profession the question whether the time has not now arrived when the policy of professional ostracism and legislative repression may not with advantage be abandoned, as a needless discredit to our loved profession, and as a method of controversy which is daily becoming more and more unpopular and ineffective;

"*Resolved*, That we earnestly suggest that the questions that now divide the medical profession into offensive and defensive factions can never reach a solution except through those methods of observation, experiment and logic which form the only effectual resort in all other departments of human knowledge."

I, for one, heartily respond to the spirit of these resolutions. I see in them and in many other things the approach of the time when personal animosity and partisan strife shall give way to fraternal respect and co-operation, and when all distinctive titles shall disappear, while whatever of truth and value those titles represent shall be established by scientific tests and universally applied in the beneficent practice of the healing art.

In closing, let me say that my ideal is an association so comprehensive as to include all competent and reputable practitioners; so liberal as to give all opinion and practice a fair hearing and an impartial judgment, and all individuals perfect liberty of thought and action; so keenly sensitive to its honor as to resist the power of lay prejudice or favor without the restraint of iron-clad by-laws or codes of ethics; and so united and strong as to command the respect of communities and legislatures, and be able to bring to bear upon them an effective influence in favor of educational and sanitary reforms.

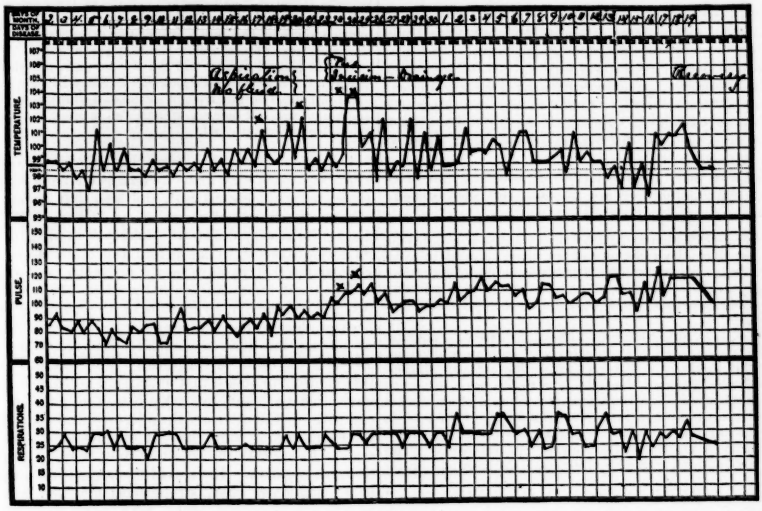
SUBPHRENIC ABSCESS, WITH SPECIAL REFERENCE TO THOSE CASES WHICH SIMULATE PYO-PNEUMOTHORAX.[1]

BY A. LAWRENCE MASON, M.D.,
Associate Professor of Clinical Medicine in Harvard University; Visiting Physician, Boston City Hospital.



THE systematic treatises on medicine and surgery make little mention of abscesses of the sub-diaphragmatic region, from the fact that they are not dependent on diseases of any one organ, but are rare sequels of various affections, and they give rise to symptoms and physical signs which are hard to classify for purposes of diagnostic differentiation. But within recent years, from the evidence of post-mortem examinations, where such lesions had been unsuspected during life and where their symptoms had been misinterpreted, as well as from the gradual refinement in the accuracy of physical diagnosis, single cases, or small groups of cases, of this description have been oftener reported in medical journals, so that it is now easy, through analy-

[1] Read before the Association of American Physicians, Washington, D. C., May, 1893.

sis of these observations, to recognize the varied etiology of these grave conditions, and, from a knowledge of their causation, to see more clearly their clinical import and therapeutic indications.

While collections of pus within the thorax may usually be detected with a fair degree of certainty, it is not so when they are seated high up under the arch of the diaphragm, circumscribed by peritoneal adhesions and with difficulty reached by the exploring needle. So that the earlier literature of this subject is largely a record of mistaken diagnoses, the true condition, in many cases, having been discovered only after death or during operation for a supposed empyema or hepatic abscess. In this relation, Bristowe, after reporting two obscure cases, says: "It seems clear that the recognition of abscesses in the upper part of the abdomen is often extremely difficult if not impossible, and that to diagnosticate them correctly demands the most careful and continued observation, and to treat them effectively calls for both skill and courage."

The gradual accumulation of observations, however, especially since the valuable article by Leyden, in 1880, on the condition which he termed "Pyo-pneumothorax Subphrenicus," [2] shows that latterly more cases have been recognized and attributed to their proper sources, and early treatment by incision and drainage has oftener led to recovery. But it is also apparent that the primary, causative lesions are of so grave a character, and the complications so serious, that cure can result in no large proportion of cases.

CASE I.

CLASSIFICATION.

In a general way such abscesses may be classified according to their situation. They may be under the right or the left wing of the diaphragm, the suspensory ligament of the liver being the dividing limit. In the former case they are encapsulated between the diaphragm and the right lobe of the liver, and are usually due to inflammation extending from the region of the liver, kidney, duodenum, or cæcal appendix. On the left they find their seat in the tissues adjacent to the stomach, the pancreas, the left lobe of the liver, or the spleen, their lower limit being formed by firm adhesions between these organs, the transverse colon, and the parietes. This is the more common position owing to the fact that the most frequent exciting cause is perforating gastric ulcer. Subphrenic abscesses, so called, are usually within the peritoneal cavity, a circumscribed peritonitis, but they may be retro-peritoneal, extending in the connective tissue behind the stomach, duodenum, intestine, or kidney. They may contain air through perforative communication with the gastro-enteric tract, or they may not. Finally, they may invade the abdominal or the thoracic cavity, more frequently the latter, thereby giving rise to the most complicated physical signs and conditions.

THE ETIOLOGY

of these abscesses and the incidents attending their course may, perhaps, be best shown by the report of seven cases, which have come under my observation at the Boston City Hospital during the past five years, with such amplifications as the literature of the subject affords. I will then consider the difficulties attending their diagnosis and treatment.

CASE I (MASON). *Abscess between liver and diaphragm; drainage; recovery.* — An Italian, aged thirty-five years, entered my service at the Boston City Hospital, with diarrhœa and iliac tenderness. He had little fever and no history of prolonged illness. The symptoms abated in a week, but ten days later abdominal pains, headache, and diarrhœa recurred. The spleen was not enlarged. Distinct diazo reaction in

[2] Zeitschrift für klinische Medicin, 1880, S. 320.

urine. Typhoid fever, dysentery, and malaria were considered and excluded. Pain at epigastrium and over liver increased, with distended stomach and vomiting, and soon the hepatic dulness was found to extend an inch and a half below the ribs in the mammary line. No jaundice. Respiration deficient at the right base. An examination of the blood showed 4,690,000 red corpuscles to 20,000 white; 1 : 235; a leucocytosis. Abscess in the region of the liver was suspected, but the exploring trocar at the angle of the scapula and in the side found no pus. A week later twenty-four ounces of inodorous pus were evacuated through the sixth space, anterior axillary line. Dr. F. B. Mallory, assistant pathologist to the hospital, examined the pus but found only broken-down material; pus corpuscles and large fatty cells; no organisms; nothing diagnostic. Dr. Edward H. Bradford, my surgical colleague, evacuated and drained the abscess through the seventh space at the anterior axillary line. Half a pint of pus escaped. The incision went through the diaphragm which was adherent to the costal parietes. The finger could feel the upper surface of the liver, but no cavity in its substance. Irrigation with boracic acid solution; baked-gauze dressing. There was a yellow or pinkish discharge containing débris, which might have been liver substance, but this was not determined. Recovery in one month.

Similar cases are the following, which I find after brief search, and they are probably not very uncommon.

Case. — Stockton and Park [3] report a case of subphrenic abscess above the right side of the liver, thought to have been due to hepatic abscess, which was cured by operation. Two years later the patient had pleuritis, septic pneumonitis, and empyema, which were also cured by incision and drainage.

Case. — Ford [4] reports an interesting case of "Hepatic Abscess with Signs of Pneumothorax," obscure respiration, metallic tinkling, and succussion. The autopsy showed complete adhesion of the right lung to the parietes and to the diaphragm. The lower lobe was the seat of an abscess which communicated, through the diaphragm, with a large abscess of the liver, thus forming an air-containing cavity which had given rise to the signs of pneumothorax. The abscess had been treated by intercostal incision and drainage.

Case. — Fyffe, [5] in an article on "Abscess of the Liver," relates the following deceptive history: A patient from India who had had dysentery presented "liver symptoms," with bulging and fluctuation of the right side. Incision between eighth and ninth spaces in front and drainage of a supposed hepatic abscess. At the post-mortem, some time later, the liver was found to be perfectly healthy, but an abscess above the liver had made several spontaneous openings.

From this and other cases the author concluded that peri-hepatic abscess in this locality may find its way out by several openings, whereas, if abscess of the liver points externally, it is generally in one direction by a single orifice, and that most frequently at the margin of the right lower ribs.

Case. — Cochrane [6] records a case of subphrenic abscess between the right lobe of the liver and the diaphragm, in which the symptoms and history had indicated hepatic abscess. Rupture into the right lung occurred and pus found exit through the bronchi. At the autopsy the liver was normal, but on its upper surface was an abscess bounded above by the diaphragm and below by the hepatic capsule, with an opening an inch in diameter into the base of the right lung.

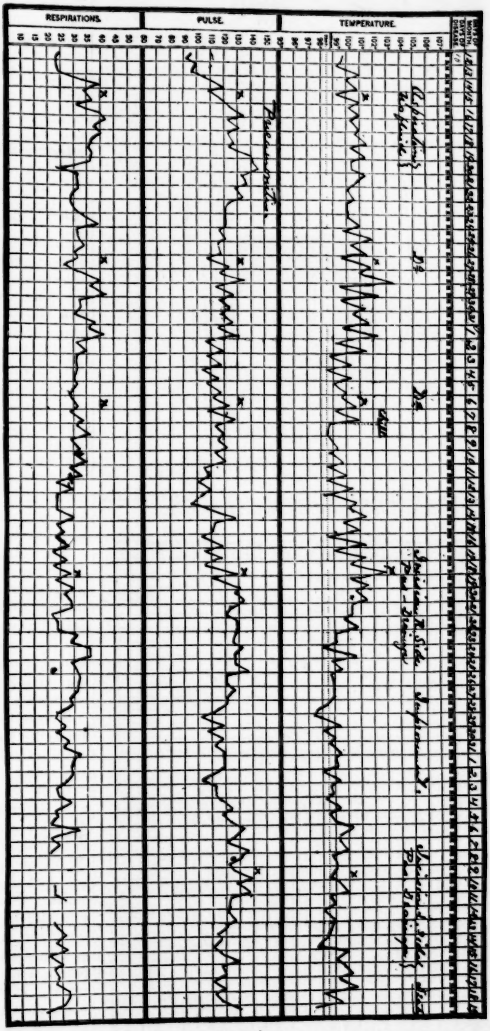
Case. — Suppurating echinococcus cyst was the cause of subphrenic abscess in a case reported by Herrlich,[7] who resected the seventh rib in the right side, incised the diaphragm, and cured the patient.

Case. — Shepherd [8] relates the case of a man, aged sixty, at the Montreal General Hospital, who was thought to have liver abscess or echinococcus cyst. He had a history of pain at the epigastrium and right hypochondrium for more than a year, with slight jaundice. A fluctuating tumor pointed at the right hypochondrium and encroached upon the thorax, causing bulging. Eighty ounces of pus were evacuated. The diaphragm was felt through the opening pushed up to the third rib in front. The liver was displaced downward and backward, but was not felt. No signs of echinococci or liver substance. Rapid recovery. The abscess was peri-hepatic.

Case. — A. T. Cabot [9] reports from the Massachusetts General Hospital, "two cases of abscess of the liver, implicating the pleural cavity," which he cured. In the first, an incision through the tenth space, posterior axillary line, showed a large abscess below the diaphragm which had invaded the pleural cavity. In the second case, a higher incision in the seventh space anterior axillary line gave exit to a few ounces of pus from a sacculated empyema. The diaphragm was felt bulging up and was incised, and a large abcess below was drained.

It is evident from these cases that subphrenic abscess of the right side may arise by extension from hepatic abscess or echinococcus cyst, and also that it may not involve the liver substance at all. The distinction during life is very difficult. Dabney,[10] in his paper on "Hepatic Abscess," read before this Association last year, states that rupture into a bronchus is the most common and least dangerous direction. He also says that the presence of liver cells in the contents of an hepatic abscess does not seem to be of very common occurrence, but that occasionally they are found and are of great value in diagnosis. Von Jaksch [11] says that it rarely happens that much aid accrues to diagnosis from the chemical examination of purulent discharges. In Cabot's cases the microscopical and chemical examinations were thought diagnostic of liver abscess. In my case the result of microscopic examination was negative. In cases of "peri-gastric" abscess, to be mentioned later, streptococci and the bacillus pyocyaneus have been found, with many other organisms and sometimes particles of food. From this source, also, round worms have escaped into the pleural cavity.

SUBPHRENIC ABSCESS IN RELATION TO PERFORATING ULCERS OF THE STOMACH AND DUODENUM.



The chief interest of this subject, however, centres upon its relation to gastric and duodenal ulcers, and the occurrence of air-containing abscesses which present signs resembling those of pyo-pneumothorax. Four such cases have come under my observation. Two of these were reported to the Suffolk District Medical Society [12] four years ago, and will be briefly recapitulated.

CASE II (Mason). *Subphrenic abscess from gastric ulcer, with perforation; drainage; cicatrization of*

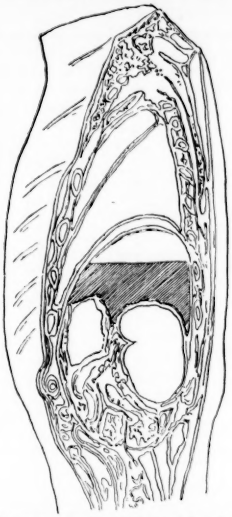
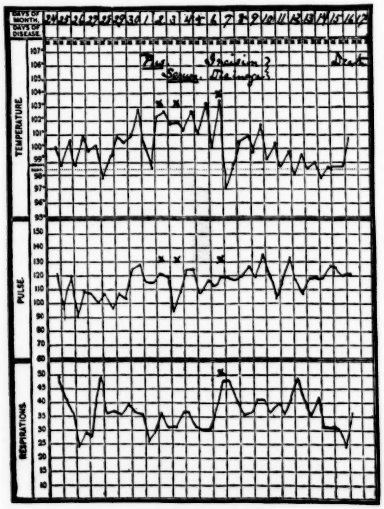
ulcer; death. — A young woman, aged twenty-two years, who had been anæmic for a year, entered the hospital December 12, 1888, with dyspepsia and gastric pain. The pain was referred to the lower margin of the ribs, and was aggravated by forced inspiration. There was fever, but vomiting, chills, and sweating were absent. She had retention of urine. In the left side and back respiration was absent below the seventh rib; tubular above, with high-pitched, crackling râles. There was no cough. Aspiration in the seventh space found no fluid. Vomiting soon became a prominent symptom, the vomitus containing pus and blood-stained shreds, with a very foul odor, as if an abscess were discharging through the stomach. These evacuations were followed by relief of pain and diminution of fever. Further explorations failed to reach the pus. Shortly, the pain was transferred to the right side in the region of the lower ribs, with tenderness over the liver, which was neither enlarged nor depressed. There was severe pain in the right shoulder. I evacuated several ounces of pus, having the same odor as the vomitus, by incision through the tenth right space, anterior axillary line, and inserted a drainage-tube, which followed the surface of the liver four inches upward and backward. The cavity was washed out with creoline solution, and closed up in ten days. In the meantime, the pain, fever, and vomiting had abated, but the consolidation in the left back persisted. In a few days gastric pain and vomiting returned, but the vomitus had lost its offensive odor. Pus was now found at the seventh left space, axillary line, and the cavity was drained, but the patient soon died from exhaustion. Cough and expectoration had been absent throughout.

Autopsy: Both pleuræ adherent to chest walls. No fluid in pleural cavities. Lower lobe of left lung solidified and firmly adherent to diaphragm. On section, it presented a granular surface, and was very dense (interstitial pneumonitis). In a space between the liver, spleen, stomach, diaphragm, and chest-wall was an abscess cavity, of three or four ounces capacity, which communicated with the incision in the left side. There was no perforation of the stomach, but in the posterior wall was a recently healed ulcer. Firm adhesions bound the above-mentioned organs together and to the parietes. The diaphragm was not perforated. The abscess in the right side had closed and the sinus could not be found. Liver, kidneys, and heart pale and opaque.



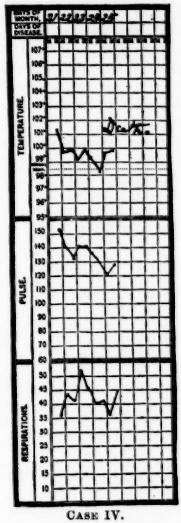
CASE II.



CASE III (Forster). *Subphrenic abscess from perforating ulcer of the stomach; drainage; death.* — A female, aged thirty-five years, entered the hospital September 24, 1890, in the service of Dr. E. J. Forster, who asked me to see her. She had had dyspnœa and palpitation for a year; abdominal pain and vomiting for a week only. No hæmatemesis. Marked tenderness in the epigastrium, left hypochondrium, and lower part of left chest. Liver one inch lower than normal. In the splenic region flatness extended from the seventh rib to a point midway between the border of the ribs and the umbilicus. Here a tumor was felt which was

stationary during deep respiration. Non-tympanitic fulness at epigastrium.

Lungs: Below angle of left scapula, flatness; diminished respiration, voice sounds and fremitus. Succussion splash. No cough. Aspiration at seventh left space, posterior axillary line, found thin, foul pus. The following day, at nearly the same level, twenty-four ounces of clear serum were withdrawn. This seemed to show a serous pleurisy and an abscess cavity below.



CASE III. — Vertical section through stomach and spleen, to show relations of air-containing abscess, as in Case III.

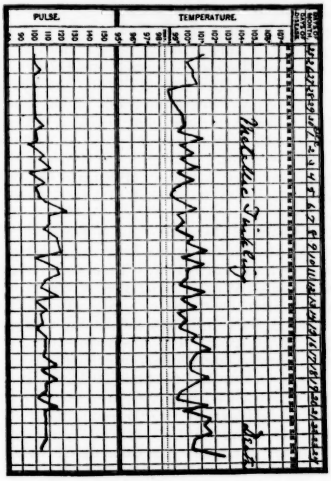
CASE III.

A diagnosis of subphrenic abscess from perforating gastric ulcer was made, and operation was advised. This was undertaken by Dr. H. L. Burrell, Dr. D. W. Cheever in consultation, although in the meantime the patient had begun to expectorate a dark, foul, purulent fluid, and was so weak that ether was not administered. About two quarts of sanious pus escaped through a free incision in the ninth space, posterior axillary line. Irrigation with warm boracic acid solution. After four days the fluid came away clear, the cavity had contracted, and the temperature was normal, but there was no gain in the patient's strength, and she died ten days after the operation.

Autopsy: Below the ensiform cartilage a cavity was opened, of large size and lined with pyogenic membrane, bounded by the liver, diaphragm, stomach and adhesions. The left lung was adherent to the chest-wall behind and to the diaphragm, leaving a pus cavity in the lowest part of the pleural sac from which was an opening through the diaphragm into the abscess below. Lower part of lung gangrenous; liver, stomach and spleen firmly adherent and removed together. Upper third of spleen softened and covered with pyogenic membrane.

CASE IV.

The stomach showed two ulcers near the pylorus, in the lesser curvature, one through the mucous membrane only; the other, one centimetre in diameter, with smooth, rounded edges, communicating directly with the abscess cavity.



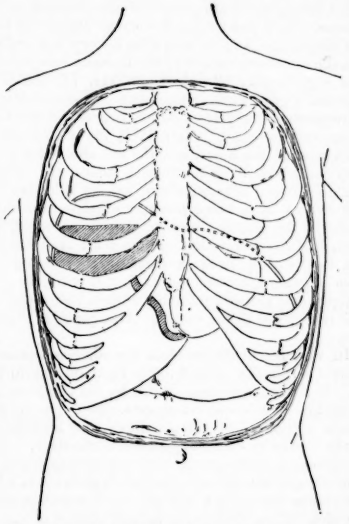
Diagnosis: Ulcer of stomach, with perforation and abscess formation above and below diaphragm.

CASE IV (Sumner). *Perforating gastric ulcer, with circumscribed peritonitis, which later became general; death.* — A Swedish young woman, aged nineteen years, entered the hospital in the service of Dr. A. M. Sumner, February 21, 1893. For a week she had had gastric pain and nausea. No vomiting nor chills. The day before admission she fell to the floor, writhing in great agony. The pain was referred to the chest, later to the abdomen. She was in collapse on admission, and failed steadily. The abdomen was tense, tender, and tympanitic. She vomited once or twice. It was noted that there was dulness at the bases of both lungs, and a friction rub in the right axillary region. On the left, tympany below the fourth rib in front and absence of respiratory sound. She died in a few days. A general peritonitis was recognized, but the patient's condition was such as to forbid extended examination.

Autopsy: An abstract of part of the autopsy, which was made by Dr. Councilman, is as follows:

The peritoneal cavity contained 1200 cubic centimetres of thin, fetid pus. There was a circumscribed cavity containing pus, shut off from the general cavity, and bounded by the suspensory ligament of the liver, the diaphragm, the upper surface of the left side of the liver, the stomach, and the parietes.

Stomach: The stomach was adherent to the liver. In its anterior wall, just beneath the attachment of the stomach to the liver, and about the middle of the stomach, was a round perforation with smooth edges, one centimetre in diameter. On opening the stomach, there was a round ulcer of the mucous membrane, two and a half centimetres in diameter, corresponding to the external perforation. It was directly in the middle of the stomach. On the posterior wall, at a point exactly corresponding to the ulcer in the anterior wall, was a small ulcer through the mucous membrane only.



Case V.

Lungs: Congested at bases; no adhesions. Apices indurated (fibrous), with numerous small caseous and calcareous masses and fibrous nodules.

Pleuræ: Diaphragmatic pleura on both sides covered with fibrino-purulent exudation, which extended somewhat over the lateral surface of the left lung; 200 cubic centimetres of turbid serum in each pleural cavity.

Diagnosis: Perforating gastric ulcer causing circumscribed peritonitis with subsequent perforation of general abdominal cavity. Acute pleurisy with exudation due to extension from peritoneum. Old healed tuberculosis at apices.

Case V (Mason). *Perforating duodenal ulcer causing abscess, with signs resembling those of pneumothorax; death; autopsy.* Male, aged fifty-six years, entered the hospital November 25, 1888. After a severe gastric attack fifteen months before, he had recovered so far that he could work, but had never felt well since. A month before admission he was again seized with violent pain in the epigastrium and right side, so severe that ether was required. He had been in constant pain since, with several exacerbations. No vomiting and no blood from bowels at any time. At the epigastrium was a tense bulging, tender and resonant. Over this area metallic tinkling was heard when the patient coughed. The liver was two inches lower than normal. Over the front of the right chest, as low as the seventh rib in the mammary line, the percussion tone was hyper-resonant, the respiration was faint, vocal fremitus diminished, and metallic tinkling was heard. At times the coin sound was elicited, but these phenomena were inconstant, were not observed in the back, and there was no succussion splash. In the lower half of the right back were signs of pleuritic effusion. The heart was displaced an inch

Case V. — Air-containing abscess above liver; sinus communicating with duodenal ulcer; as in Case V.

and a half to the left. The removal of twenty-four ounces of clear serum by tapping at the fifth right space, posterior axillary line, gave relief to the pain and dyspnœa, and the epigastric bulging and tenderness disappeared temporarily, as well as the metallic tinkling. I had expected to find pus, thinking that a circumscribed pyo-pneumothorax was present, and I was at a loss to explain the signs, as this was the first of these cases which had come under my observation. Later tapping withdrew more serum, but no pus, the presence of which had been expected by Dr. Samuel Delano, who attended the case in its early stages, when the symptoms pointed rather to some abdominal affection. The patient failed gradually, and died in one month. There were no chills at any time. Cough and vomiting were slight. No pus was found in the stools.

Autopsy: Right lung adherent to diaphragm. Serous effusion in posterior right pleural cavity. Diaphragm not perforated. No pneumothorax. Lungs healthy. Between the right lobe of the liver at its

highest part and the diaphragm was a large, circumscribed abscess, partly filled with pus, which communicated by a long sinus with an open duodenal ulcer one and a half centimetres from the pylorus. This ulcer was circular, one and a half centimetres in diameter, with smooth edges, and from it extended a fistulous tract running on the under surface of the liver, between the gall-bladder and the longitudinal fissure, to the anterior border of the liver, then up the superior surface until it entered the abscess cavity. The gall-bladder, duodenum and liver were adherent, thus shutting off the abscess from the peritoneal cavity.

REMARKS.

These four cases present in typical form the incidents which attend the course of subphrenic abscess when due to perforating ulcer of the stomach or duodenum. Two had a clear history of symptoms below the diaphragm and in two this history was wanting, but the secondary nature of the thoracic complications was suggested in all. In Cases III, IV and V the physical signs which accompany pyo-pneumothorax were present in a greater or less degree. Case V was to me very obscure. The fluid in the pleura, the displacement of the heart, and the metallic sounds were very misleading. The abscess under the arch of the diaphragm, covered above by the adherent lung and behind by a large pleuritic effusion, was out of reach by the ordinary means. It was observed, however, that the respiration and the vocal fremitus were not totally suppressed in front as they would have been in general pneumothorax, but it was only at the autopsy that the air-containing abscess above the liver was recognized as the cause of these peculiar phenomena.

In very few instances does the abscess caused by gastric perforation extend to the right side as in Case II. It is almost always limited by the falciform ligament, but occasionally an abscess, due to gastric ulcer which perforates near the pylorus, may seek its way to the convexity of the right lobe of the liver. I find but one case with perforation of the cardiac end of the stomach and one through the posterior wall in which this course was taken; and but one in which perforating ulcer of the duodenum caused abscess of the *left* side.[13] Eisenlohr[14] mentions the case of a girl in whom, at autopsy, was found a perforating gastric ulcer of the posterior wall, communicating with an abscess above the right lobe of the liver, which during life had given rise to tympany and metallic tinkling below the right scapula.

Therefore, an air-containing abscess under the left ala of the diaphragm almost invariably indicates perforating ulcer of the stomach, usually of the middle portion, in the lesser curvature; and most frequently in the posterior wall. Whereas a similar abscess between the right lobe of the liver and the diaphragm points to perforation of the duodenum or vermiform appendix. I find but two instances in which abscess under the left wing of the diaphragm was traced to an appendicitis.[14]

Empyema and true pneumothorax are not infrequent results of perforation of the diaphragm from below, but the adhesion of the lung to the diaphragm and costal pleura tends to check this complication. The abscess may also be evacuated through the bowels or the bronchi, as in Case III. Serous or sero-purulent pleural effusion, from contiguity with the subphrenic abscess, is more common.

Fenwick,[15] in his interesting clinical lectures at the London Hospital on "Some Obscure Diseases of the Abdomen," mentions eight cases of peri-gastric abscess and five cases of "peri-duodenal" abscess as having occurred at that hospital during the past forty years. He also collected reports of fifty-one peri-gastric abscesses from various sources. Forty-one were caused by gastric ulcer, six by cancer, and four by lesions not connected with the stomach. While gastric ulcer is more common at the pyloric end, the greater fixity of the cardiac extremity is thought by this writer to favor the adhesions which admit of the formation of abscesses, as it is found that these usually communicate with ulcers in the lesser curvature nearer the cardiac orifice. In twelve cases the thorax was invaded, but in others there was empyema without perforation of the diaphragm. In twelve cases the abscess found exit through the parietes, and in three the pericardium was perforated, causing death on the third or fourth day. Pneumo-pericardium may supervene. Two-thirds of the patients were female, and the symptoms were often of many years' duration. Fever and pain were prominent symptoms, but repeated chills were not noticeable. Both true and false pneumothrorax were often recorded. Pus from the abscesses in some instances contained food. In five cases the perforation of the stomach was found to have healed, as in Case II.

At that hospital there were also five cases of "peri-duodenal" abscess during the same long period. Of twenty-four cases which Fenwick had collected, eighteen were caused by perforating ulcer of the duodenum, three by gastric ulcer, five by suppuration from gall-stones which burst into the duodenum, and one by hydatids of the liver. The ulcers were usually near the pylorus; they were seldom in an acute stage. The edges were smooth and thickened. In two cases the pus had made a cavity in the pancreas, and in five suppuration had extended to the connective tissue behind the duodenum. "Peri-duodenal" abscesses were more common in males. Nine out of eleven cases in which the sex was mentioned were in men. In one case the symptoms had existed for eight years, in another seven, in a third three, the ulcers having become quiescent, thus forming adhesions. Pain, radiating from the epigastrium, was the most notable previous symptom, but this was not always urgent. In most cases there had been vomiting of blood or bloody discharge from the bowels. Emaciation and exhaustion were often extreme. Tumor at the epigastrium was the most frequent sign on inspection, usually elastic, often tympanitic, and sometimes giving a metallic tinkling. The line of tympany in certain cases varied with the position.

I have been able to find no instance of recovery from this condition and know of no case in which a perforation of the duodenum has been found healed after death.

(To be continued.)

THE POSTMASTER-GENERAL has announced that disease germs, no matter how securely sealed, are to be classed with unmailable articles.

QUARANTINE *vs.* SANITATION.

BY W. T. SEDGWICK, PH.D.,
Massachusetts Institute of Technology, Boston.

A MEMORANDUM of unusual interest has lately appeared defining the attitude of Great Britain towards quarantine. England has always held a leading position in sanitary affairs, so that her steady refusal to adopt wholesale quarantine at her seaports has naturally excited frequent comment and inquiry. It has seemed very strange to many that the nation having the largest commerce, and therefore most exposed to cholera and other exotic diseases, should be so indifferent, and even opposed, to quarantine. Sanitary officials of the political kind, such as too often exist in this country, have naturally supposed that England's opposition to a mediæval system was based upon merely mercenary motives — these always offering to minds of a certain order an ample explanation of unusual action. Sanitarians, however, have long known that local isolation was the key-note of the English system, together with local sanitation, which should make widespread outbreaks impossible even if exotic diseases like cholera should be imported. To apply a saying of Pettenkofer, the English have regarded unsanitary conditions as a kind of powder for which cholera is a spark: and they have held that it is wiser to keep no powder than to spend their energies in frantic attempts to beat off a spark, which, if it gets in, would be sure to blow them to pieces. Quarantine, and that, too, of a very rigid kind, is employed in England; but it is quarantine of the individual rather than the mass, a system now generally described by the term "isolation of the patient."

The memorandum referred to was compiled at the request of the Foreign Office with a view to its circulation amongst British representatives abroad, and to its serving as an answer to a number of requests made by foreign countries as to the action taken in England for the prevention of the spread of infection. It was prepared by Dr. Thorne Thorne, medical officer to the Local Government Board, and himself a distinguished sanitary authority, in answer to a request of the Foreign Office to be supplied with a statement "setting forth the general nature of the standing precautionary measures adopted in the United Kingdom to prevent the introduction of contagious or infectious diseases." In reply, Dr. Thorne states that even in the case of cholera, the Public Health Department of Great Britain recognizes no system of quarantine. He adds:[1]

> For nearly fifty years past it has been held that reliance on a quarantine system would be, to a large extent, impracticable, and that any attempt to carry it out would be injurious, both by reason of engendering a false sense of security and by affording a pretext to sanitary authorities for avoiding expenditure of those local funds on which, in this country, we depend alike for effecting large schemes of sanitary improvement and for carrying out our current sanitary administration. Hence, our principal trust has been in securing amendment in every way in the sanitary circumstances under which the population are living; and defence against cholera in this sense has been supplemented by the adoption of a series of cholera regulations which apply to our ports and coast line and which are aimed at preventing the introduction of cholera by means of shipping. . . .
>
> If, as the result of examination, the medical officer of health certifies a ship to be infected with cholera, the ship must be moored at a specified place, and every person on board is required to submit to examination. Every person who, as the result of that examination, is not certified to be suffering either from cholera or from any illness which the medical officer of health suspects may prove to be cholera, is permitted to land immediately on satisfying the medical officer of health as to his name, place of destination, and address at such place. This information is communicated to the sanitary authority at the place of each such person's intended arrival, and it is for that other authority to take measures (which commonly include a visit for some five consecutive days, on the newly-arrived person) such as may be expected to prevent extension of cholera should that disease appear in any one after arrival in their district. Any person on the ship who is certified to be infected with cholera is required to be removed to a hospital provided by the sanitary authority. Should the condition of the patient not permit of this, the ship is detained under the control of the medical officer of health. And any other person certified to be suffering from an illness which it is suspected may prove to be cholera, can similarly be detained for the purposes of diagnosis for a period not exceeding two days. The ship is required to be disinfected and other precautionary measures have to be adopted as regards drinking-water, bilge-water, infected articles, dead bodies, etc., after which she is at once released.
>
> The only instance in which any further measure of restriction can be applied is as to persons on board a ship which, though not infected with cholera, either carries passengers who are in a filthy or otherwise unwholesome condition or has come from a place infected with cholera. If, in any such case, the medical officer of health deems it necessary to intervene, with a view to checking the introduction or spread of cholera, he is required to give a certificate to that effect. When such certificate has been given no person is allowed to leave the ship unless he satisfy the medical officer of health as to his name, place of destination and address at such place, such information to be utilized in the same way as in the case of a ship certified to be infected with cholera. But beyond this there is no right of interference either with the vessel or with those on board.
>
> The English cholera regulations do not profess to be so framed as to prevent all chance of the importation of cholera into the country. They aim at detection and arrest of all actual or suspected cholera at our ports and at giving the earliest possible warning to inland authorities as regards particular persons about to arrive in their respective districts. If, in spite of these measures, the disease should be imported, every sanitary authority has the responsibility for the maintenance of conditions which should enable them to deal with imported cholera in such a way as to prevent its extension.

[1] Lancet, July 1st and 22d, 1893.

In a lecture recently delivered at St. Bartholomew's Hospital, Dr. Thorne spoke more informally about the English system substantially as follows:

Up to a recent date the Continental Powers had relied essentially upon a rigid quarantine system. Quarantine, as applied to the Thames, for example, would mean the detention of all vessels coming from infected ports for a period varying from ten to five days according as the conclusions of the Constantinople Conference or of the Rome Conference were accepted. During that period healthy and sick alike would be prohibited from having any communication with the shore. If, during the quarantine detention a case of cholera occurred on board, the whole of the crew and passengers, together with the ship, would have to go through a second period of detention and so long as any fresh attacks occurred. In the meantime shipping would be accumulating and the result for us would become a mere absurdity. And not only so, but half-a-crown would any night secure a boatman's service for landing on the river banks. In short, the system would only have to be applied to ensure its immediate breakdown.

England decided against quarantine for another reason. If the people in this country were told that a line had been drawn round England to keep out cholera, a death blow to our sanitary administration would at once be dealt. Since they have been told that cholera cannot, with certainty, be kept out of the country, and that they themselves must be prepared to deal with it if it is imported by maintaining their districts in such a sanitary condition that the disease shall not spread if it should make its way into them, eight millions sterling have been spent in sanitary works every year and hundreds of thousands of lives have been saved from typhoid fever and other epidemic diseases. The general mortality has also largely decreased and a Frenchman — an old fellow-student of his — who is now at the head of the public health service in France, has calculated that, according to the estimate of human life by Dr. Farr and other English authorities, taking all the millions we have spent and all the lives that have been saved (I forget the exact sum), we have just got our money back. It might almost seem as if we had done it on purpose. No greater calamity could happen to this country than to apply the system of quarantine. At Dover alone in one week in August, 5,800 people arrived at the port. What would Dover have done had she been obliged to quarantine them? They could not have them in the harbor at night, for they could easily have escaped; they could not have them on land for a similar reason. If they had put them to sea they would probably have been sunk by the first tempestuous wind. The attempt would be perfectly ridiculous and could be attended by nothing but disaster.

Quarantine was also a cruel process. That was best exemplified by reference to land quarantine, as, for example, during the Egyptian outbreak of 1883, when villages and communities were surrounded by troops with loaded rifles and bayonets. Any person taking food within the prohibited line would be subject to the same quarantine as the villagers, and it is believed that land quarantine has often destroyed more lives by starvation and misery than would have been sacrificed by cholera. But land quarantine, too, is essentially inefficacious, the line being broken without difficulty, whether in Egypt or elsewhere, by all who can afford to pay their tribute of baksheesh.

The following is especially interesting and suggestive:

For England the abandonment of quarantine has been an almost unmixed good. The knowledge that no pretence would be made to keep out all chance of cholera in this country, has done more perhaps than anything else to induce our sanitary authorities to spend their money on great works of sanitation and on such improved sanitary administration as is likely to prevent the spread of any imported disease of the type of cholera. Millions have been spent to this end; but, on the other hand, hundreds of thousands of lives have been saved. Even if cholera should once more succeed in passing the barrier of our ports and diffusing itself inland and cause a heavy mortality, we should still be enormously the gainers in point of human life by the system which we have so deliberately adopted; but there is no doubt that our system is rather calculated to prevent than to lead to such a contingency.

No one can successfully deny that these principles embody sound sense as well as a rational application of the best results of modern science to sanitation. In our own country at present there is still altogether too much of leaning upon federal quarantine. This has its place; but our great cities ought to understand that their first and principal business is to set their own houses in order; to see that their own sanitary affairs are in intelligent hands, and, especially, that their public food supplies, such as milk, ice and water are free from all taint of sewage. Efficient local sanitation and isolation — not so much wholesale, by quarantine, but for each particular case — these are the plain teachings of modern science as well as of common-sense.

TENOTOMY.[1]

BY A. M. PHELPS, M.D., NEW YORK,
Professor of Orthopædic Surgery in the University of New York, the New York Post-Graduate School and Hospital, and the University of Vermont, etc.

THE question of tenotomy has been under discussion for more than half a century, and, as yet, seems to be unsettled in the minds of the profession. We have, on one hand, the enthusiastic tenotomist who believes in performing tenotomy under almost all circumstances without rhyme or reason; and on the other, the gentlemen who believe that tenotomy should never be performed, but by mechanical means all the deformities can be overcome. It is needless to say that there is a middle course to pursue which I believe to be correct; and it is more particularly to this that I desire to call your attention this evening.

Muscles are composed of fibrous tissue, between the layers of which are deposited the muscle cells. These muscles end in tendons, which are inserted into the various levers of the body.

When one of these muscles becomes contracted from various causes, a deformity always ensues. This deformity, when of the extremities, is of a very serious character, and the question arises when and how shall we lengthen these tendons? It is true that muscles in which change has not already taken place in their fibrous element, can be lengthened by stretching, whereas muscles in which the fibrous element has become permanently shortened, it is almost an impossibility without a cutting operation to lengthen. Barwell has given to the first class the name of contraction, and to the second, contracture.

To determine just when a muscle is contractured and not contracted is often very difficult. Sayre years ago laid down what he calls a law, and I quote from his paper of October, 1886, printed in the *Virginia Medical Monthly*, the following: "When a contracted tissue is put upon the stretch, and the parts are brought as nearly as possible into their normal position, either by means of the hands or mechanical aids, and then additional pressure is made upon the tissue that is stretched either by making pressure upon the stretched tissue with the fingers or by pinching it between the thumb and fingers, and no pain or voluntary spasm is caused, the tissue thus stretched and handled is simply contracted, and can be elongated by persistent traction and treatment. If, on the contrary, this additional or 'point pressure,' upon an already stretched tissue causes pain and an involuntary contraction or spasm of the muscles of the entire body, the tissue thus stretched has become contractured or changed in its structure, and must be severed before the parts can be brought into their normal relations."

It is undoubtedly true, that putting a contractured muscle upon the stretch and making pressure upon it will produce pain and often spasm; but the same is true of muscles which are not contractured. I have in a long series of cases, particularly in contractions of the adductor muscles in hip-joint disease, demonstrated that spasm and pain under point pressure are present in those muscles which rapidly give way under extension. We are all familiar with the spasm which is elicited in certain forms of spinal disease, producing ankle clonus. If, in this condition, the muscle is put upon the stretch and point pressure made, pain and spasm is elicited, notwithstanding, by a little prolonged force, that foot may be placed in position of extreme flexion upon the leg.

Then we must say that it cannot be a law; that it is good so far as it goes to aid in diagnosis; but I know of no positive way of determining when a muscle is contracted or contractured. I usually place these patients under ether, and with great force, with my hands or with a machine, attempt to place the limb in the normal position. If, when it arrives at a certain point, I find resistance, requiring great force to overcome it, tenotomy is invariably resorted to.

All cases of contraction of fibrous tissue producing deformity I believe are better divided than stretched. It is a well-known fact that when fibrous tissue, whether of the muscle fascia, or ligament, is submitted to prolonged traction, pain, spasm and often convulsions will result, for example, Dupuytren's contraction of the fingers. Then, inasmuch as we have no law upon which we can depend, and the physician must use his own judgment in a given case, I have long been accustomed from experience and from clinical observation to follow out the following rules:

In small children with contractions, I invariably begin a system of manual treatment supplemented by braces usually made of plaster-of-Paris to hold that which I have gained by manipulation. These manipulations are conducted day after day until the child

[1] Read before the Orthopædic Section of the New York Academy of Medicine, December 16, 1892.

arrives at a certain age — as for instance in club-foot, usually two or three months — when I proceed to divide whatever parts are contracted and overcome the deformity. In cases of paralysis resulting in contractions, I usually operate. I frequently operate upon these cases, even where the deformity can be overcome, because the lengthening of the muscle materially assists the brace in holding the member in the straight position and aids the antagonizing to contract.

It is argued by the gentlemen who see nothing beyond steel bars, buckles, straps, ratchets and screws, that to cut a tendon necessarily impairs the usefulness of the muscle, and that non-union of tendons frequently occur; that they overcome these contractions by machines.

To the first I will answer that the cutting of a tendon does not impair the usefulness of the muscle to the same extent that stretching with a traction machine does; the sheath of the muscle making lateral pressure. Cases of club-foot treated by prolonged traction show precisely the same or even more atrophy of the calf, and no better feet than those operated upon.

Some of the gentlemen who were present at the tenth International Congress in Berlin, will remember the excellent cases of cured club-foot by forcible redressment presented by Professor Wolff. In all of those cases, there was the same marked atrophy of the calf that we observe in cases upon which operations have been performed. There is a reason for this. The constant pulling upon a muscle in which the fibrous element has become shortened, produces atrophy of that muscle by making pressure upon the muscle cells by the approximation of the fibrous element of that muscle. When a tendon is cut, the muscle contracts. All of the muscular element is left, the tendon is lengthened, and when the muscle is again restored to its normal tone it is as strong as before cutting. The muscle is stronger than those stretched. As regards the non-union of tendons, I will say that, in my own practice, extending over a great many hundred cases, I have never seen a case of non-union of tendons, and non-union of tendon, in my opinion, will never take place, if the operator exercises proper care and performs his operation according to scientific methods. That non-union of tendon does take place when performed according to the idea of some authors there is no doubt. The adhesions to the sheath and the pulling out of the tendon into a long ribbon-shaped piece, as recorded by Adams, when performed as many English surgeons perform it, is a fact, and this is one of the best reasons why the methods as adopted by them, both of operating and carrying out of the after-treatment, should be abandoned; because when tenotomy and the after-treatment are carried out, as I shall soon describe it, these calamities will never be seen.

This brings us to a consideration of how long is the orthopædist justified in employing mechanical treatment in a given case before resorting to tenotomy. I believe that, if he has control of his patient, he is not justified in carrying on mechanical treatment for the lengthening of muscles, fascia and ligaments in any case for a longer period than a very few weeks unless the progress is very marked. Mechanical treatment covering a period of years, for the purpose of stretching tissue, is certainly at this age of the world entirely unjustifiable. The application of mechanical means for the stretching of fascia in all instances should be abandoned. We have only to look back a few years and in many of the older text-books, and some of the modern, we find machines for curing Dupuytren contraction of the finger, by a traction machine. Those cases all relapsed. The orthopædist was driven into disgrace, and the surgeon reaped the fruits of honest labor performed. And so it is with the fascia of the sole of the foot, the fascia in other portions of the body, the ligamentous contraction producing hammer-toe, and a great many other varieties of contracted fibrous tissue that I might enumerate.

These are clearly cases for the knife. That is not to say by use of instrumental work covering periods of month and years it is not possible to overcome many of these deformities; but unless careful bracing is continued after the stretching has been done, and even then the cases will surely relapse, and they usually do relapse, as is evidenced in the contraction of the finger that I have just mentioned. We have emerged from the cloud of septic ignorance into the bright sunshine of antiseptic progress, and to-day the objections which were urged against the operative work no longer hold good.

How shall these operations be performed? There are three methods now of lengthening tendons and fibrous tissue, namely, subcutaneous work, open incision, rupturing by force.

We will first consider subcutaneous tenotomy. Subcutaneous tenotomy should be performed upon all tissues which can be easily reached and divided with a knife without danger of cutting important blood-vessels or nerves. Nearly all of the tendons of the extremities can be with safety cut subcutaneously, and certainly one would never think of performing a large operation when a smaller one would do. And then again, when an open operation is performed, adhesions, sepsis and wound infection are more likely to occur than in subcutaneous work. Tendons passing through fibrous canals, as for instance those of the finger, should not be operated upon in the fibrous sheath, because adhesions usually follow. There is, however, at the present time, but little danger from wound infection, and I have no serious objection to an open incision being performed. It should be, however, resorted to only where there is danger of cutting important blood-vessels or for other reasons than to simply divide a tendon or nerves. The tendo Achillis, I believe, should always be divided subcutaneously. Dr. Wilson, of Philadelphia, has done some excellent work upon the tendon by open incision. He resorted to a method which I have resorted to a great many times — which I will allude to later — of splitting the tendon, cutting each half off in opposite directions, and suturing it. Keene, I believe, is given credit as being the author of the operation. Lange claims priority, and so do others. I will here add that in 1888 before the class of the Post-Graduate School, Dr. Abbe being present, and at his suggestion, I performed the same operation upon the biceps tendon of the forearm, through an open wound, lengthening the tendon several inches. The result was perfect. This, I think, antedates anything that has been published upon the subject.

I now perform upon the tendo Achillis and the biceps tendon the same operation, only I perform it subcutaneously, introducing the knife over the tendon, splitting it and cutting it out both ways, allowing it to slip up and lap. In this way I have lengthened the tendon

two inches and a half. The split in the tendon in that case was made one and one-half inches. The ends remained in contact.

The sterno-mastoid muscle should always be divided by an open incision along the clavicle. The iliacus internus and psoas muscles should always be divided at their attachment to the lesser trochanter by an open incision beginning at the greater trochanter and extending down the leg four inches. With a periostotome one can work over the femur, hugging it closely, and with safety detach the tendon from its attachment. I did this once subcutaneously, and ligated the femoral about ten minutes after. I would do open incision to lengthen the biceps of the arm, or split the tendon subcutaneously. Open incision should be performed when the ham-string tendons and all tissues are shortened. This is a favorite operation of Schede's, of Hamburg. I have performed the operation many times, and now have a case in Charity Hospital which I will hope to have the honor of presenting to you at some future meeting.

I mention these three because they are the tendons with which we have more frequently to do. The fasiculus given off from the tendon of the ring finger should be removed with an open wound to make the hand more useful for piano playing. Open incision when performed on the sole of the foot for the relief of talipes varo equinus is not performed for the exclusive purpose of seeing just what is being cut, but to lengthen all the shortened tissues which hold the foot in the abnormal position.

RUPTURING OF TISSUE BY GREAT FORCE.

This is, in the treatment of club-foot, usually employed together with tenotomy of important tendons; ligaments and fascia at the same time being ruptured by force. Under other circumstances I do not believe that it should be substituted for either subcutaneous tenotomy or open incision.

After the contracted parts have been divided by one of these three methods, how will the limb be dressed? What will be the after-treatment? The teaching, in vogue in England by many as well as in this country, is to divide these parts and leave the limb in the deformed position, allowing union to take place between the tissues and then gradually stretch them to place. This was frequently followed by non-union of tendons, by adhesions which ruined the future usefulness of the member and brought the operation into disrepute, and it led many of the orthopædists of England and America to employ instrumental means and discard the knife entirely. To this most unscientific procedure Sayre struck the death-blow in a very able article, in which he urged, and gave his own experience, the immediate correction of the deformity, allowing the severed ends of the tendon to separate. This procedure, in my opinion is scientific, and during the many years that I have employed it in hundreds of tenotomies, I have yet to see the first case of non-union or material impairment of the functions of the tendon.

Over-correction of any deformity should be practised. I have seen tendons separate six inches, and still a perfect reproduction was the result.

When open incision has been performed, the same methods of dressing and after-treatment should be followed. The wound should be, if possible, closed and dressed antiseptically, the parts should be kept at perfect rest for at least six weeks after the operation, after which, if deemed advisable, suitable braces can be applied.

To illustrate the difference of opinion which exists among various orthopædists, I desire to present to you a case this evening, together with its history, of a very interesting deformity of the feet. This boy is thirteen years of age, born in London, was a patient of Mr. Adams in London, referred by him to Dr. L. A. Sayre in this city. He was treated under Dr. Sayre's direction for one year. He was suffering from partial paralysis which had produced a shortening of the tendo Achillis, which drew up the heels. As he walked, the tendency was to throw his foot inward and I have no doubt that, before many years, he would have developed a double talipes varo equinus. Mr. Adams when he referred him to Dr. Sayre, placed a very severe injunction upon the mother to allow no American to operate upon his tendons, else the feet would surely be ruined.

After he had been with Dr. Sayre for one year with no improvement, the mother then consulted a well-known conservative orthopædist of this city, who advised her to do nothing, but to build up his physical condition. She then consulted a third, Dr. Shaffer, who informed her that by applying interrupted traction with his machine, for one or two years, he thought he could cure the deformity. The mother consulted me on September 23d, and I informed her that I believed that tenotomy of the tendo Achillis should be performed (the feet could not be placed at a right angle with force). On September 25th, assisted by Dr. Plympton, Dr. Goodwin and Dr. Steele, of St. Louis, I performed the operation and immediately placed the feet in the super-corrected position. They were kept in this position for six weeks and were again put in plaster for two or three weeks more. He was allowed to walk with the plaster-of-Paris until the braces were adjusted. The tendons were lengthened two and one-half inches, and upon examination, I think it will be difficult to determine where the new tendon begins and the old ends.

I quote this case to illustrate the difference of opinion existing in the orthopædic profession.

An interesting case came to my office, aged fifty three, C. J. Cole, of Greenwich, Conn. It was a case of double talipes varo equinus, operated upon when he was twenty-four months old, by Dr. Hubert, of Utica, N. Y.; subcutaneous tenotomy of both Achillis was performed. After-treatment was carried out by bandages. I found, fifty-one and a half years after the operation, the following condition: Feet perfectly staight, calves well developed, tendons firmly united and much enlarged at point of union. There was an osseous deposit in this new material. He went through the war, had no fatigue, never felt any weakness in ankle or calf. It was a reproduction of one and one-half inches of tendon. This is interesting because it is almost one of the first cases of tenotomy ever performed.

This brings us to the consideration of the subject of reproduction of tendons. Gluck, in 1884, performed some very interesting experiments. Among others, was the reproduction of tendons by the introduction of catgut, in the track of the tendon. He also introduced tendons from the lower animals and reports excellent results.

I wish to report a case, which I presented to the

Surgical Section of the Academy of Medicine in 1891, April meeting. The record book of that meeting gives a correct report of the case, whereas the report as made in the *Medical Record* of August 8, 1891, makes no notice of the points which I now will present to you. The man had had an incision through the wrist which had suppurated, cutting the median nerve and all the tendons of the wrist; sloughing had destroyed many of the tendons for a distance of six and eight inches. The tendons of the ring finger and the little finger, were uninjured. The tendon of the index finger and of the thumb was destroyed for a distance of six in one, and eight inches in the other.

At Charity Hospital in February, 1891, I performed the following operation: After removing all cicatricial tissue, dissecting out and suturing the nerve, I found the condition as described above. I united the muscle which went to the middle finger to the tendons of the ring and little finger, and united the distal end of the tendon of the middle finger to that of the ring finger, I then, with catgut, sewed in between the ends of the tendon of the index finger, a distance of eight inches, four or five strands. I did the same thing with the thumb, a distance of six inches. The hand was placed in the supra-flex position, after the ulnar nerve had been united and the wound closed, and left it for three weeks. Within one week sensation had returned to the paralyzed hand and at the end of three weeks the man was able to move all of his fingers. When the case was presented at the Academy of Medicine, he was capable of moving the index finger and thumb. When he was discharged from the hospital, he had very good motion of all of the fingers, excepting the middle, ring and little finger, they moving together. The index finger and thumb moved separately. Here was an instance of a reproduction of eight inches of tendon of the index finger and six of the thumb, by means of catgut. In this case an anastomosis was established between muscle which had no tendon or was useless, to tendons which communicated with other fingers.

It is quite practical, where tendons are lost, to introduce strands of catgut, or tendons from the lower animals and reproduce them.

THE QUESTION OF ANASTOMOSIS OF TENDONS.

Where the power of one tendon is lost, it is quite practical to attach to that tendon another tendon of a muscle which is not paralyzed; or, as in the case already quoted, where tendons are, to a considerable extent, destroyed, it is better to unite them and the muscle to a tendon lying contiguous. To illustrate: April 21st, this year, I repeated an operation which I had performed many times for other conditions, but for the first time in a talipes calcaneus. Willett's operation has not proven all that was hoped for it. Judson has offered a very fair and just criticism of Willett's operation. Therefore, I decided in this case to perform an original operation. There was total paralysis of the gastrocnemius and soleus. I made an incision down upon the tendon, divided it, severed the tendon, stitched it together. The long flexes of the toe were not paralyzed. These were divided at the inner malleolus, the distal ends firmly stitched to the periosteum, and the proximal ends to the tendo Achillis, hoping that these muscles would take the place of the paralyzed gastrocnemius and soleus. The foot was dressed at right angles, redressed at the end of three weeks, redressed again at the end of four weeks. Now he comes to us to-night, the final dressing to be removed and the shoes adjusted; and I present him for your examination. We must bear in mind that this foot has been fixed almost three months in plaster dressing, and it will not be expected that he will have much muscular control over it. The splint which I shall adjust now is Judson's, which he will wear for six months or a year, after which I will either present him here to you or report on the case. Electricity and massage will be employed.

Quite recently, Dr. B. F. Parish, reported to the *New York Medical Journal*, October 8, 1892, a similar case upon which he operated in May 25, 1892, for the relief of flat-foot by grafting to the anterior tibial tendon some of the long extensors, hoping thereby to hold up the arch of the foot. What the ultimate result will be can only be determined by time. Believing that flat-foot is not produced by paralysis of the anterior tibial tendon, I cannot see that much will be gained by this operation. He claims priority of grafting a muscle paralyzed or useless to one vital or useful. My wrist case was performed in Charity Hospital in February, reported to the Academy in April, and published soon after in their reports. The French and Germans had already grafted tendon to tendon in similar cases in 1874 and 1876, so there is nothing really new under the sun.

Clinical Department.

A USEFUL METHOD OF DRAINAGE IN SUPRAPUBIC CYSTOTOMY.

BY FARRAR COBB, A.M., M.D.,
Surgical House-Officer at the Massachusetts General Hospital.

The most difficult thing in suprapubic operations on the bladder where constant drainage must be kept up is to drain off the urine by siphonage with any degree of success at all. In the majority of cases the lining membrane of the bladder is in a state of chronic inflammation, suturing is contraindicated, and the wound in the bladder and abdominal wall must be left wide open.

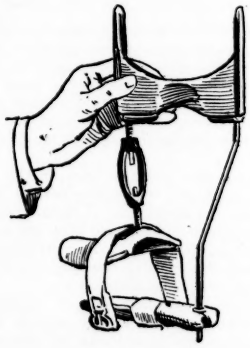
In a recent case under my care, in the service of Dr. H. H. A. Beach, after trying several methods of drainage and finding that all of them sooner or later flooded the patient and bed and kept the wound filled with a pool of urine the following method was devised, and has worked admirably, draining the bladder perfectly and keeping the patient dry:

An ordinary glass drainage-tube rounded at the lower end with a collar at the top, such as used in abdominal wounds, was passed into the bladder and into this was pushed for its whole length a wick or tight roll of iodoform gauze while the free end of this about three feet long was drawn through a flexible rubber-tube and led over the side of the bed into a bottle, thus establishing capillary drainage through a set of tubes. It was found that no gauze could be used to pack the wound around the tube because of its capillary action defeating somewhat the perfect work of the gauze in the tubes. The recti muscles hold the glass-tube firmly enough and the wound is best packed with absorbent cotton thoroughly impregnated with oxide of zinc ointment which acts as an efficient dam and

antiseptic dressing and prevents any irritation of the skin. Over this dressing and around the juncture of the rubber and glass tubes a light dressing of gauze or cotton can be loosely fastened. In this case it kept dry for twelve hours at a time. If the bladder was sucked dry after each dressing with the ordinary suction apparatus in the glass tube and then the combination gauze and tubular drainage used it was found that the gauze drained away the urine as fast as it was secreted. With this method it was found necessary to dress the case only once or twice a day and yet the patient kept perfectly dry. The gauze wick in the tubes was changed only once in twenty-four hours. It was found that this method did away with the annoying pain and tenesmus which before was obstinate.

No mention of this use of gauze drainage has been found by me and it has proved of so great value in securing almost perfect drainge in these hitherto very troublesome cases that I have been led to thus briefly describe it.

New Instruments.



APPARATUS FOR FRACTURE OF THE HUMERUS THROUGH OR NEAR THE DELTOID INSERTION.

BY Z. BOYLSTON ADAMS, M.D., M.M.S.S., FRAMINGHAM, MASS.

APPLICATION.

(1) THE arm is bent at a right angle and supported by a fillet at the wrist.

(2) The crutch is pressed firmly into the axilla, the lower splint put under the forearm, while the brass rod is adjusted behind the elbow and fastened by nuts to the splint.

(3) The upper splint is then placed over the arm as near the elbow as possible, and the double screw is turned until firm and equal pressure is made upon the extremities of the crutch.

(4) Straps are now put on to hold the two splints in connection upon the forearm, and the broad piece of webbing buckled around the elbow keeps all in place.

EXPLANATION.

The fleshy tendons of the pectoralis muscle in front and of the latissimus dorsi behind, are shortened by the pressure of the crutch in the axilla. The crutch is of peculiar shape adapted to the object. By this pressure upon the borders of the axilla, the deltoid is completely *antagonized*, and the upper fragment drawn inwards.

The extension applied between the elbow and forearm below and the crutch above, straightens out the *biceps* (especially the long head), and the *triceps*, which being closely related to the bone, back and front, are found to fix the fragments in their true relation.

No coaptation splints are required, the screw and nuts permitting exact adjustment of pressure and bringing the bone into line.

EFFECT.

There is no discomfort; all pain and swelling disappear; and at any time the surgeon can put his fingers on the broken bone. The result is found to be all that could be wished.

This apparatus was designed and used for the left arm of a man of five feet six inches. It can be easily reversed for the right arm, and allows some lengthening for a larger subject.

A NEW HOSPITAL FOR NEW YORK. — A new hospital to be known as Grace Hospital will be begun next fall in New York. There will be a main hospital and three independent buildings for old men, old women and children.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

Eighth Annual Meeting, at Washington, D. C., May 30, 31 and June 1, 1893.

(Continued from No. 7, p. 172.)

FIRST DAY. — AFTERNOON SESSION.

ON A SIMPLE CONTINUED FEVER,

by Dr. G. Baumgarten, St. Louis, Mo.

In St. Louis and vicinity, and without doubt in other localities of the Mississippi Valley — during the past fifteen years, and perhaps longer — cases of continued fever have been met with which are often interpreted as typhoid fever, and by many called typho-malarial, (though differing *toto cælo* from Woodward's "typho-malarial") — a fever which is characterized by high temperature, even hyper-pyrexia, a sudden onset rather than a gradual rise, a fever curve of greater irregularity than a typical typhoid, a duration of from two and one-half to five weeks, sometimes terminating by crisis instead of lysis, a total absence of local symptoms or signs of localization, and such general symptoms only as may fairly be ascribed to the high temperature itself. It has no relation whatever with malaria, and in my estimation it differs so widely from typhoid fever that it cannot be classified with the latter without doing violence to the classical definition of typhoid. It is not, in its classical features, a walking typhoid, nor an abortive form, and its persistent, and often extreme, high temperatures, preclude the idea of a *mild* form.

In the absence of all localization, and ignorance of the (evidently infectious) pathogenic cause, I am tempted to adhere to the provisional name by which I have privately called it these fifteen years, a *febris continua simplex*. In 1888 my colleague, Dr. P. G. Robinson, presented to the Association a paper on the same disease, observed in the same locality, and I have little doubt that it has been alluded to in the paper of Dr. I. E. Atkinson, of Baltimore, in 1887.

During the past autumn, St. Louis was visited by an epidemic of typhoid fever, chiefly in the months of October, November and December. Both before and during this period, there was also an unusual increase in the number of cases of the continued fever in question. It then became the subject of more than ordinary observation and comment by many physicians, and the incisive points of difference between the two classes of cases were generally recognized.

Dr. I. E. Atkinson believed that the cases recorded by Dr. Baumgarten were varieties of typhoid fever. Typhoid is the almost universal continued fever; and most of the continued fevers that are from time to time written about are sooner or later relegated to the class of typhoid fever. Mountain fevers, mucous fevers, gastric fevers, nervous fevers and typho-malarial fever have all become classed as typhoid fever. Typhoid, especially in children, is often atypical. It is a common thing for all of the characteristic symptoms of typhoid, except fever, to be absent in children. We often see cases running quite different courses which are due to the same origin. We need a good deal more evidence to make us accept the existence of another independent continued fever.

Dr. Baumgarten thought it was reasonable to suppose that there were continued fevers developed by the specific typhoid germ, and others, running a similar course (as far as the fever was concerned) that were not so caused. We certainly have no proof that the cases described are cases of typhoid fever. It would not be surprising if bacteriological investigation should prove these cases to be identical as to their origin with typhoid fever, but still the desire to separate them as a clinical form would not be amiss in view of the bearing upon treatment.

CREASOTE IN THE TREATMENT OF TUBERCULOSIS,

by James T. Whittaker, Cincinnati.

Creasote has no real influence upon the fever of phthisis. The writer has tested this fact in every way. Though the patient be saturated with the drug by every avenue — by the stomach, by the lungs, by the bowels, by the skin, by all these methods at once — creasote does not control the fever.

Creasote acts on the stomach. It excites the appetite and lessens the distress of indigestion. Most patients improve decidedly for a time under the immediate change of nutrition.

In the study of the action of a remedy in tuberculosis we must have more definite knowledge of the nature of tuberculosis and what it is that is to be accomplished. In this regard there is now more definite knowledge. It is now known that the whole character of consumption, that is, tuberculosis pulmonum, was not determined by the discovery of the bacillus tuberculosis. It is now known that tuberculosis of the lung is at least not a pure process. Other organisms are associated with the tubercle bacillus in tuberculosis pulmonum, and to them are due some of the symptoms, especially the hectic fever. Streptococci are the associated organisms in the majority of cases. Creasote has probably no effect upon the streptococcus infection, because it shows no real effect upon the liver. It inhibits the growth, or actually destroys some of the organisms which induce fermentation in the stomach and intestine without interfering with the actual processes of digestion, and thus contributes to the cure of consumption — as does arsenic, hydrochloric acid, etc. — through the avenue of nutrition. Considered from a clinical standpoint, creasote holds its place. It is an easy routine practice and is perfectly harmless in any dose. In Dr. Whittaker's wards at the Good Samaritan Hospital all the tuberculous patients are put upon creasote immediately upon entry. Five drops of a mixture of creasote and tincture of nux vomica (or, where strychnine is contraindicated, tincture of gentian) are given in a teaspoonful of whiskey and a tablespoonful of water three times a day after meals. The dose is increased by one drop daily up to ten, whereupon additional doses are given at 10 A. M., 4 P. M. and at bedtime. The body shows signs of saturation at sixty drops per day. All of his cases in non-febrile periods are treated with tuberculin, which remains the only specific remedy for pure tuberculosis, but which has no effect (or only a bad effect) upon septicæmia.

Dr. Wood thought that in the rage of bacteriological study physicians often forgot that they ought to treat the individual sometimes and not the bacteria. Some years ago every phthisical patient was dosed with sulphuretted hydrogen. The results were, at first, said to be very extraordinary, but in a few months all the syringes and sulphuretted hydrogen squirts in general were relegated to the past. Creasote seems

to be running through very much the same history. Both sulphuretted hydrogen and creasote are valuable remedies, but neither of them acts in any way specifically upon the bacillus; they do good by their action on the individual whois the unfortunate host of the parasite.

DR. TRUDEAU, of Saranac Lake, said that the tubercle bacillus bore cheerfully a good deal of medication that was disastrous to its host. In his experience in animal tuberculosis, no matter how large the dose of creasote injected, the disease developed regularly in its natural course. It seemed to him that in phthisis it did good by improving the condition of the stomach and intestinal canal, and he had not quite discontinued its use. Like arsenic, if it improved the appetite it was well to keep it up, but if it disagreed with the stomach it should be omitted. It was in no sense a specific.

THE INTESTINAL ORIGIN OF CHLOROSIS,

by F. FORCHHEIMER, Cincinnati.

The conclusions of this paper: (1) Chlorosis is due to oligochromæmia. (2) Chlorosis is the result of faulty hæmopoiesis. (3) In chlorosis the fault in hæmopoiesis lies in diminished hæmoglobin production. (4) Hæmoglobin is principally formed in the intestine, proven (*a*) by direct investigation upon lower animals, and (*b*) indirect observation upon the human being. (5) Hæmoglobin formation can be increased by the introduction into the intestine of agents not containing iron, but preventing putrefaction. (6) Chlorosis is due to a prevention of hæmoglobin formation, by destructive agents acting upon the precursor of hæmoglobin in the intestine.

With the object of determining whether hæmoglobin was formed in the intestine, Dr. Forchheimer conducted a series of experiments upon rabbits with the following results: During full intestinal digestion the animals were put upon the rabbit-holder, the abdominal cavity was opened, and blood was examined from the terminal brauch of the mesenteric artery and its accompanying beginning of the mesenteric vein. Care was taken to open the blood-vessels as near as possible to the entrance or exit, so that arterial blood was examined immediately before it went into the capillaries of the intestine and venous blood directly as it came from them. Forty observations gave the following average:

In the artery: red corpuscles, 5,362,000; hæmoglobin, 78¾ per cent.
In the vein: red corpuscles, 4,546,000; hæmoglobin, 78¾ per cent.

The deductions derived from this were: The number of red corpuscles is diminished in the veins, while the quantity of hæmoglobin remains the same; therefore hæmoglobin is absolutely increased in the vein, and each red corpuscle carries more hæmoglobin in the vein than in the artery. The dilution of the venous blood, during digestion must be taken into consideration. This would probably also account for the diminution of red corpuscles. If the blood contains 78¾ per cent. hæmoglobin before going through the capillary circulation, takes up fluid there, and comes into the veins containing 78¾ per cent., it certainly follows that the hæmoglobin is increased in the veins. Each red corpuscle carries about 18 per cent. more of hæmoglobin in the veins than in the artery.

The results obtained in the treatment of 11 cases of chlorosis, all females, varying in age from fifteen to thirty-five years, by the use of salol and hydronaphthol were as follows: There was steady increase in hæmoglobin; the smallest amount gained in one week was 5 per cent., the greatest 20 per cent. With the rise in hæmoglobin all the patients began to improve. The nearer 80 per cent. the more the symptoms began to disappear; and from ordinary examination, without blood test, most of the patients would have been willing to have been discharged as cured. Hydronaphthol seemed more efficacious than salol, the results being more quickly obtained, and the rise more rapid.

DR. J. P. C. GRIFFITH, of Philadelphia, considered Dr. Forchheimer's contribution one of great value. He has shown chlorosis to be distinctly an intestinal disease, analogous to pernicious anæmia but distinctly different from it.

DR. H. C. WOOD considered Dr. Forchheimer's paper one of the most interesting that he had heard read before the Society. In view of the fact that the test relied upon for hæmoglobin was a color test, he desired to know whether any control experiments had been made between arterial blood taken from the finger and venous blood taken from the finger, to see if there was not an apparent rise in the hæmoglobin in the simple transversion of capillary into venous blood.

DR. FORCHHEIMER, replying to Dr. Wood, said that all possible precautions had been taken in the examination of the blood. Both arterial and venous blood had been examined, and the estimations were the results of many examinations.

EXPERIMENTAL OBSERVATIONS CONCERNING THE NATURE OF CHOREA,

by DR. H. C. WOOD, Philadelphia.

Dr. Wood's paper covered the following points:

Function of inhibition everywhere an important one in the animal system.

The spinal cord no exception to this.

The various choreic movements may originate either in the brain or in the spinal cord.

The spinal choreic movements largely the result of the loss of inhibition.

The St. Vitus Dance of children, the whole nervous system evidently involved.

The reflex phenomena of St. Vitus Dance are in accord with the theory that spinal inhibiton is depressed. Difficulty of explanation under other theories.

The action in chorea of certain drugs which have long been believed to affect spinal inhibition in accordance with the theory.

Relations of quinine to the theory, and the probability of its value as a practical medicament. Practical studies of the quinine treatment in animals and in man.

Dr. Wood's experiments with quinine cover two series of cases. The first series were upon chorea in the dog. Case 1: Setter; chorea seven months' standing; quinine; immediate great improvement and recovery in a month. Case 2: Pointer; chorea of long standing; quinine, twenty-four grains a day at first; no improvement; increased to forty grains daily, followed by complete recovery in two weeks. Case 3: Violent chorea; dog could not stand; quinine, sixteen grains daily; completely cured in twenty-five days. Case 4: Chorea improved on quinine treatment, but dog died. Case 5: Improvement under quinine, but dog died. Case 6: Specially violent chorea; quinine; cured. Canine chorea is a very intractable disorder, and previous to the introduction of the quinine treatment, a number of cases treated the past year gave not one favorable result.

The second series of cases were cases of chorea in children. The first two cases were treated in the Hospital of the University of Pennsylvania. Case 1. M. D., seven years. Chorea so bad she could not feed herself at all. February 3d, quinine treatment begun. In a week the child could feed herself. Improved steadily, and was discharged March 28th, entirely well. No other treatment except cod liver oil. Case 2. Jessie ——, ten years. Entered hospital February 3d, with chorea of four years' standing. Could not feed herself. Put on quinine. Could feed herself in a week, and has steadily improved since. Of nine cases treated in the University of Pennsylvania Dispensary by quinine, only two failed to improve; and of these cases one failed to improve upon arsenical treatment, but the second was relieved by Fowler's solution.

The result of clinical studies seemed highly favorable to the use of large doses of quinine in the treatment of chorea. A remarkable fact in the cases most carefully watched, was the complete absence of apparent physiological action. A child of ten years of age took 1,200 grains of quinine in the course of seven weeks, having part of the time taken day after day twenty-four grains a day with no physiological symptoms, only a steady growth in the general nutrition.

Dr. Whittaker thought Dr. Wood's results were extremely interesting, but that the investigations were defective in one regard — in that there was no examination made of the blood of the choreic dogs. Chorea is sometimes a manifestation of malaria, and it would be very interesting to know if malaria in the dog manifested itself as chorea.

Dr. Wm. H. Welch replied to Dr. Whittaker's observations, that Dr. Berkley and himself had made a careful study of the pathological anatomy of chorea in the dog, and examined the blood in one case. A protozoic organism was found in the intestines; but cover-slip preparations did not show the presence of the malarial or other organism in the blood.

Dr. William Osler did not consider Dr. Wood's results to be in any way extraordinary. To treat a disease like chorea with a drug which does good only within ten days or two weeks is not very satisfactory, and not much better than arsenic and other remedies.

SUBPHRENIC ABSCESS,[1]

by Dr. A. L. Mason, of Boston.

Dr. S. J. Meltzer, of New York, read a paper on the same subject.

In the differential diagnosis between subphrenic abscess and empyema we cannot rely exclusively on physical signs, neither altogether upon the etiology. By the physical signs, we cannot decide whether the fluid is located above or below the diaphragm. The objections to the unexceptional reliance upon the etiology are that there are a few cases of subphrenic abscess the primary cause of which is located in the cavity above the diaphragm, and there are cases of intrapleural effusion with an exclusive and pronounced abdominal history. A case in point was a child of twenty-six months which after an attack of pneumonia had what was supposed to be an empyema. Upon opening the pleural cavity very little pus was found but the diaphragm was found to bulge up into the thoracic cavity, and through it distinct fluctuation was discovered. The abscess was evacuated and drained, and the child made a complete recovery. This subphrenic abscess following pneumonia, was doubtless caused by the preceding pneumonia. Another similar case has been reported by Gæhde. The micro-organisms of these abscesses are probably the same that usually are found in meta-pneumonic empyemata, namely, the pneumococcus lanceolatus or the streptococcus pyogenes. We have to assume that they passed directly from the lesion in the lung into the space below the diaphragm into the lymph channels. Then there is a class of cases of empyema succeeding to pronounced abdominal symptoms: (1) those originating from gastric ulcer perforating directly into the pleural cavity; (2) those which accompany or follow several acute abdominal troubles, like typhoid fever, peritonitis, etc.

Dr. Wm. Osler briefly alluded to cases of subphrenic abscess which had come under his observation. The first case gave a history of dysentery. There were symptoms of abscess of the liver; diagnosis of pyo-pneumothorax subphrenicus; operation; recovery. The probable source of this abscess was in the appendix as at the operation Dr. Halsted was able to pass his finger far down into the flank reaching quite to the crest of the ilium. A second case was one of pyelonephritis, tuberculous colitis, with perforation of the splenic flexure of the colon and a formation of a perinephritic air-containing abscess. Incision and drainage, pulmonary tuberculosis and death. There was a remarkable air-containing tumor over the right kidney opposite the tenth, eleventh, and twelfth ribs, particularly interesting from the fact that it was resonant when the patient was on his abdomen but dull when he turned on his side. The third case was an instance of subphrenic abscess following an empyema. There had been an injury to the arm and back, amputation of the arm, erysipelas three weeks after the accident, signs of inflammation at the left base, development of pyo-pneumothorax, expectoration of fetid pus, septic fever, asthenia, and death. The sequence of events in this case was, wound of the kidney, subphrenic abscess, empyema, perforation of diaphragm and lungs, with discharge of pus. Two other cases of subphrenic abscess were operated upon by Dr. Halsted both making satisfactory recovery. The diagnosis in one case was that of liver abscess and the diagnosis in the other case was posterior empyema and it was not until the opening was made in the chest that it was discovered that the pus was subdiaphragmatic.

Dr. W. H. Welch thought that the withdrawal of a portion of the pus with a hypodermic syringe, and finding in it a mixture of bacteria, and particularly the presence of the bacillus coli communis, would make it strongly suspicious that the abscess communicated with the cavity of the alimentary canal. The presence of the colon bacillus in pleural effusions is extremely rare. He had never seen a case like that reported by Dr. Meltzer. He regarded Dr. Meltzer's explanation as the most plausible one. He did not think it necessary to assume that the direction of the lymph current was a decisive factor, for micro-organisms could travel with or against the current of the lymph channel. Peritonitis is widely recognized as a possible complication of pneumonia. The micro-organism is capable of setting up inflammation anywhere.

Dr. R. H. Fitz considered the term "subphrenic abscess" a clumsy one and thought it would be much better to consider this class of cases under the head of "subphrenic peritonitis," because the latter designates the anatomical condition present and includes cases

[1] See page 186 of the Journal.

where one has to deal with pus and also cases of serous peritonitis. In thus emphasizing the peritonitic nature of the processes we are led more directly to the etiology and also more directly to what is perhaps the best region for the treatment of this class of cases. When the thoracic element is considered too particularly the tendency is to operate through the thoracic walls, whereas the beneficial results which often occur are favored by an operation considerably below.

(To be continued.)

Recent Literature.

A Text-Book of the Theory and Practice of Medicine. By American Teachers. Edited by WILLIAM PEPPER, M.D., LL.D., etc. In two volumes, illustrated. Vol. I. Philadelphia: W. B. Saunders. 1893.

This text-book of the Theory and Practice of Medicine is offered to the medical profession and the large body of American medical students by some of the teachers of practical medicine in leading schools of this country; and the editor claims that it may be said to represent truly the best teaching of the science and art of medicine at the present time in this country. The names of the editor and of the other contributors suggest a fair basis for this claim, and an examination of the various articles in detail indicates that they have for the most part contributed the good work which might be expected from them.

The contributors to this first volume are Drs. J. S. Billings, William Pepper, J. T. Whittaker, W. Gilman Thompson, H. C. Wood and William Osler. The paper, the type, the illustrations and the general make-up of the book — a royal octavo of 900 pages — are excellent, and justify the choice of the publisher.

Elementary Physiology for Students. By ALFRED T. SCHOFIELD, M.D., M.R.C.S., etc. Small 8vo, pp. 372. Philadelphia: Lea Brothers & Co. 1892.

This is a small book, with many of the vices of its class, and few redeeming virtues to make it in any way better than its numerous fellows. Among its virtues must be reckoned the exceedingly well printed illustrations, gathered for the most part from standard authorities and generally familiar acquaintances of long standing. The best of the set is made up of two handsomely colored pages of microscopic specimens, the worst is a picture of the Anglican form of a "Davidson" syringe, illustrating action of heart and valves. The text is largely collated without very careful consideration and almost exclusively from English writers or translations; it is not always complete or fresh (for example, liver, p. 98), and is sometimes very inexact, as, for example, in the account of the Young-Helmboltz theory of color perception, and especially in the statement of Hering's views.

Electro-Therapeutics of Neurasthenia. By W. F. ROBINSON, M.D. 16mo., pp. x, 72. Detroit: George S. Davis. 1893.

In this little volume the author omits all considerations of symptomatology or other methods of treatment. His directions are clear and explicit, but our own experience has not led us to put as much value upon the therapeutic action of electricity in neurasthenia, or to lay as much importance upon the various details of application. The whole book might well have been condensed into a brief article.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 24, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE PAN-AMERICAN MEDICAL CONGRESS.

ON September 5th, the first Pan-American Medical Congress will open in Washington. Preparations for this Congress, which have been going on for more than two years, and which have entailed an enormous amount of work are now practically completed; and we have as a result a programme, or rather a series of programmes, with several hundred papers to be read before twenty-two sections. Among these papers are many which promise to be of the first importance, and the programme, as a whole, insures the success of the meeting.

The establishment of an international medical congress limited to the Western Hemisphere comes appropriately in the year dedicated to the memory of Columbus. An attempt was suggested to bring into closer relationship the different American nations, the two sections of which have always been more closely allied with Europe than with each other. A committee was appointed by the American Medical Association in May, 1891, the result of which was a resolution passed by Congress in July, 1892, by which the President of the United States was authorized and requested to invite the several governments of the Western Hemisphere to send official delegates to the meeting of the Pan-American Medical Congress, in September, 1893. All of the countries, practically, have appointed official delegates in response to this invitation, and the President will open the Congress in person. A large number of the colonies and a great many municipalities have also appointed delegates, as have the medical organizations throughout Latin-America. In this country a large number of well-known men have accepted different official positions, and have otherwise contributed to the success of the meeting. The number of names is so large that a congress of these contributors alone, if they all attend, would be numerically of good size.

The general regulations of the Congress provide for

the different officers and committees, but the time and place of future meetings is left for later consideration. The sections of the Congress are: General Medicine, General Surgery, Military Medicine and Surgery, Obstetrics, Gynecology and Abdominal Surgery, Therapeutics, Anatomy, Physiology, Diseases of Children, Pathology, Ophthalmology, Laryngology and Rhinology, Otology, Dermatology and Syphilography, General Hygiene and Demography, Marine Hygiene and Quarantine, Orthopædic Surgery, Diseases of the Mind and Nervous System, Oral and Dental Surgery, Medical Pedagogics, Medical Jurisprudence, Railway Surgery.

The official languages are English, Spanish, French and Portuguese.

It will be noticed that the subjects of the papers are more than usually specialized by the large number of sections. This cannot fail to increase the interest and attract discussion in subjects often lost in a more general section. The Governors of nearly all of the United States have appointed delegates to represent the sanitary interests of their respective States. These latter number nearly three hundred in the aggregate. It will be seen, consequently, that special interest attaches to the Section on Marine Hygiene and Quarantine, and on Hygiene, Climatology and Demography, in charge respectively of Surgeon-General Wyman, of the Marine-Hospital Service, and Medical Director A. L. Gihon, of the United States Navy. In both of these sections, discussions on different questions of public importance have had time allotted to them. The Section on Medical Pedagogics, the programme of which will be found on page 180 of the JOURNAL, is a new idea, and one which promises to be of such interest and importance, especially to medical teachers, that its adoption by other congresses may be expected.

The organizers and readers of papers have done their work, and it now remains for the profession at large to attend the meeting, and for each to do his share in discussion. At the close of the meeting the foreign members will visit different cities of the country, in many of which arrangements have already been made for their entertainment. In this way the medical resources of the country can be better shown and our hospitality better proved than by the more formal gathering at Washington.

ANÆSTHETICS AT THE LONDON HOSPITALS.

THE *Medical Press* has recently published a series of reports from the anæsthetists of eleven chief London hospitals upon the method of administering anæsthetics. They are most interesting and full of valuable details.

To most of American readers the statements regarding the use of ether will be not a little surprising. Nine of the eleven hospitals give a decided preference to ether as the best and safest anæsthetic, and while all make a more general use of chloroform or a mixture of chloroform and ether than is done here, they nevertheless use ether in a majority of the cases. The two exceptions to this use were at the Royal Free Hospital where ether "though strongly favored when possible," is not used to a great extent, and Kings College Hospital, where a mixture of alcohol, chloroform and ether, in the proportion of one, two, and three parts respectively, is used in nearly every case.

The reports showing differences in detail of administration are quite agreed as to the greater safety and usefulness of ether and the general class of cases when it is undesirable. Nearly all of the hospitals use nitrous oxide for minor operations, such as are done in an out-patient department. The majority use chloroform for children and persons of advanced age, or those suffering from bronchial disease; Dr. Hewitt, however, gives it in bronchitis and emphysema without trouble. Dr. Bourns, of Westminster Hospital, is inclined to use ether even for very old persons, as he thinks the general dread of ether inhalation in old persons is somewhat groundless, and when lung troubles follow an operation on an etherized old person it is more likely the result of exposure of the chest and the cooling effect of carbolized towels packed about the patient than due to the ether vapor.

Many of the statements are strong and decided. Mr. Ward, of St. George's, says: "I do not use chloroform unless there is a good and sufficient reason to give the coroner in case of a catastrophe"; though he considers chloroform safe if given with great care. Mr. Braine, of Charing Cross, says: "Ether is by far and away the most popular anæsthetic at this hospital, being administered to over seventy per cent. of the cases; chloroform is only administered when the nature of the operation compels its use, as in operations upon the mouth, tongue, or where from existence of lung troubles ether is contraindicated." At the London Hospital Dr. Hewitt says: "Ether is the anæsthetic now principally used. It is administered about twice as often as chloroform. Some few years ago a precisely opposite state of things existed, but an extensive and open-minded comparison of the two has resulted in a distinct preference for ether." The main consideration which has led to a more extensive employment of ether is this, it has been found that "hairbreadth escapes" and fatalities have conspicuously decreased in frequency since the change in practice has been effected.

Many of the hospitals begin the anæsthesia with nitrous oxide before giving the ether, and claim to have a quieter, quicker result with less ether, than if they began directly with the latter.

The ether is given through an inhaler in nearly every case, and apparently much less is used than in many of our hospitals. The Clover's inhaler is chiefly used, though Ormsby's and Junker's have many advocates. Great stress is laid on having the anæsthetic freshly supplied each day, the remaining portions in the bottle not being used again.

A not uncommon practice seems to be the use of both ether and chloroform in the same case at differ-

ent times, as, for instance, when under ether the patient shows a tendency to bronchial irritation or vomiting, the ether is removed for a while and chloroform used in its place. Again, at St. Mary's, "Drunkards and half-starved, broken-down patients require very careful management. We commence with ether, and when we reach the stage of excitement, which is pronounced, give a little chloroform and resume the ether when the patient is quiet and breathing well."

A noticeable fact in reading these reports is the undoubted advantage to be derived from a thorough and systematic supervision of the management of anæsthesia such as is the case in the London hospitals where there is an official anæsthetist to direct and give instruction to the students and house-officers in etherizing.

TREATMENT OF ALCOHOLISM BY LARGE DOSES OF STRYCHNIA.

THE treatment of alcoholism by strychnia has found many advocates in Russia, especially since the clinical observations of Tolvinsky and Partivisky in 1887. They gave strychnia by the mouth, in doses increasing from the sixtieth to the thirtieth of a grain three times a day. These doses seem small, but the results reported were favorable. The experiments of Jarokeosky on dogs in 1888 led him to formulate the conclusion "that strychnine enables the animal organism to receive large quantities of alcohol for prolonged periods without any apparent injury to the central nervous system."

Pombrak, another Russian authority, found strychnia a valuable remedy both in cases of chronic alcoholism and in those of dipsomania, "not merely curing the attacks, but abolishing the desire for drink." Even attacks of delirium tremens were influenced beneficially. He began with doses of one thirtieth of a grain; in more severe cases with one fifteenth of a grain.

It is worthy of note that Luton of Rheims first called attention to the remedial effects of nux vomica in alcoholism nearly twenty years ago. He was in the habit of administering one half grain of the extract or ten drops of the tincture three times a day in alcoholic trembling, in the cerebral troubles due to alcoholic poisoning, etc. It was Luton who called nux vomica the medicine of drunkards. Luton, however, recognized that nux vomica can have no beneficial effect when the alcoholism has arrived at the phase of plastic infiltrations and of granulo-fatty degenerations. Luton afterwards made trial of strychnine in hypodermic injections, and found that this drug when thus administered had marvellous efficacy in delirium tremens. Dujardin-Beaumetz adopted this mode of treatment in delirium tremens, with equally favorable results. He uses the following prescription:

Sulphate of strychnia	10 centigrammes.
Cherry laurel water	10 grammes.
Distilled water	10 grammes.

A hypodermic (Pravaz) syringeful contains five milligrammes (one-twelfth of a grain). In cases of furious delirium he makes an injection every half hour till four injections are given; then every hour, till the delirium is subdued. It is not an uncommon thing to practise these injections till two to four centigrammes (one-third to two-thirds of a grain) of strychnia are thus administered; and this treatment is pronounced "safe."

Lécuyé, a pupil of Luton, who in 1882 wrote a treatise on "Alcohol and Strychnine," reports similar successes in the use of strychnine, and considers this drug as the remedy *par excellence* of the nervous, cardiac and gastric troubles of alcoholism.

The strychnine treatment of alcoholism has been tried in this country and in England with varying success, and has been adopted in many institutes for the cure of inebriety as a part of routine practice. Experience seems to be daily justifying some portion at least of the claims made for this drug by the enthusiastic advocates of its use in the treatment of alcoholism (and not the least of its merits is said to be its wonderful power of sustaining the heart under conditions of extraordinary depression), but it cannot be relied on to the exclusion of other remedies as nerve sedatives and hypnotics, or of the proper hygienic treatment.

MEDICAL NOTES.

A LONG UMBILICAL CORD. — A case of an abnormally long umbilical cord is reported from Philadelphia. The child, a female at full term, was delivered after an ordinary labor. The cord measured 53 inches and was coiled around the neck four times.

A QUARANTINE OF LEMONS. — Surgeon-General Wyman has ordered that lemons imported from Naples be refused entry during the cholera epidemic in Italy. This order affects Boston less than New York as most of the lemon supply coming to Boston is brought from Palermo or Messina and not from Naples, ples, and lemons from the latter port only have been prohibited.

INSPECTION OF STATE QUARANTINES BY THE MARINE-HOSPITAL SERVICE. — The Solicitor of the Treasury has given his opinion that it is within the intention of the National Quarantine Act of February 15, 1893, for the Government to authorize the inspection, by proper officers connected with the Marine-Hospital Service, of the condition of State or local quarantines. Although the act does not expressly provide for the inspection of local quarantines by the Marine-Hospital Service, it appears clearly all through the act that such was the reasonable and fair intention of the law. The decision is therefore based upon the well-established and familiar principle of law that whenever a power is given by a statute everything necessary to make it effectual or requisite to attain the end is implied, and when a statute gives a right to impose a duty it also confers by implication the power necessary to make the right available or to discharge the duty. (Suth. on Stat. Cons., sections 341, 343, 344, 345, 390.) And statutes relating to the public

health are to be liberally construed. (Dwarris on Statutes.)

Yellow Fever. — No new cases of yellow fever have occurred at Pensacola. At Brunswick, Ga., there have been two cases and one death, that of the quarantine officer of the Marine-Hospital Service.

Cholera. — No new cases have occurred in New York this week, and but one death among the patients at quarantine who are all now convalescing. In Naples, the epidemic is declining, at least according to *official* reports. There are now about fifteen new cases each day and eight deaths. A few scattered cases have occurred in inland towns. In Russia, the disease is increasing very markedly, especially in Moscow, where there are some fifty new cases and twenty deaths daily. In Nijni Novgorod, the disease appeared last week, with one hundred and five deaths. Galicia has already had thirty deaths. In Hungary, there have been forty deaths each day in the valley of the Black Theiss. On the 17th, the cholera reappeared in Astrakan and Baku. Three deaths from cholera occurred in the eastern quarter of Berlin August 16th, but so far no new cases are reported.

A Hazardous Experiment. — Dr. Watkins, of New York, who was inoculated last year in Paris with a culture of cholera spirillum and recovered after a severe illness, has recently been inoculated at the Loomis Laboratory in New York, with a pure culture of the bacillus of tuberculosis taken from phthisical sputum. He believes that a healthy person, whose blood does not contain the so-called "third corpuscle," is absolutely immune to the bacillus. He has repeatedly examined his own blood and never found the dangerous corpuscle. If he unfortunately overlooked any of these third corpuscles and becomes infected it is only to be hoped that he will be able to cure the disease, as he claims he can, by the early eradication of the "tubercular blood corpuscle," or hematoblast, from the blood.

Diagnosis of Epilepsy by the Urine. — Dr. Gilles de la Tourrette claims that a diagnosis between hysterical epilepsy and that due to neoplasm can be made by the examination of the urine. He has found that there is an increase in the elimination of urea and phosphates during a convulsion due to a tumor, while the amounts excreted during an attack of hysterical epilepsy are diminished.

NEW ENGLAND.

Delegates to the Pan-American Congress. — Governor Russell has appointed John G. Blake, M.D., and J. Collins Warren, M.D., of Boston, Z. B. Adams, M.D., of Framingham, and Thomas Kittredge, M.D., of Salem, delegates to the Pan-American Medical Congress at Washington.

NEW YORK.

Bacteriological Diagnosis of Diphtheria. — President Wilson, of the Board of Health, has made public the report submitted at the last meeting of the Board by Dr. H. M. Biggs, pathologist to the Department, on the result of Dr. W. H. Park's investigations relating to the bacteriological diagnosis of diphtheria during the past fourteen weeks. A few months ago the number of cases of diphtheria reported in the city became so large as to create considerable alarm, and the Board of Health (as already mentioned in the Journal) took steps to ascertain whether many of the cases so reported were not in reality instances of what is now known as false diphtheria, that is, lacking the characteristic Klebs-Lœffler bacillus of true diphtheria. With this object in view, Dr. Park was appointed to the position of bacteriological diagnostician of diphtheria; and under his supervision culture tubes were prepared and distributed to various druggists throughout the city for the free use of the medical profession. Dr. Biggs reports that out of 431 cases examined between May 6th and August 12th about one-third have proved to be false diphtheria; 301 being true diphtheria, and 130 false diphtheria.

Professor Von Helmholtz's Visit. — Professor von Helmholtz, the world renowned eye specialist and inventor of the ophthalmoscope, arrived on August 16th by the North German Lloyd Steamship *Lahn*. After a short stay in the city as the guest of Dr. Herman H. Knapp, he left for Chicago. A number of other distinguished German physicians and scientific men came on the same steamer.

A Broken Neck. — Still another case of a man living with a broken neck is reported. The patient, who is in one of the Brooklyn hospitals, fractured the sixth cervical vertebra in diving from a spring-board sixteen feet high into five feet of water at Bath Beach. While the body is paralyzed from the waist downwards, the man is otherwise in good condition, and there seems now to be a prospect of his living indefinitely.

Miscellany.

SOME RESULTS OF FAITH CURE.

The reports from a recent faith-cure convention have some curious and interesting statistics. Out of two hundred cures reported thirty patients had made a diagnosis of organic disease; and there were the usual number of fractures which had been marvellously reunited by faith. There was no record made, however, as to the subsequent position and deformity. The time of this method of cure appears to be much shorter than that required by surgical means — as one case of a broken ankle was said to have been cured in five minutes.

The greatest curative effect of faith seemed to be upon erysipelas, for one hundred cases of speedy cure were reported. In what way the streptococcus is affected by a profession of faith was not clearly explained.

The only case not curable by this means appeared to be rupture of the heart; for one person testified

that by faith his child had been cured of colic, and a daughter of pneumonia. Their little one had been taken from them, but not by sickness; he died of a broken heart.

The further gathering of figures and the compilation of mortality statistics should not be neglected; for their results are curious and of some psychological interest.

THE HYPODERMIC USE OF NITRO-GLYCERINE IN EPILEPTIC CONVULSIONS.

THE occasional usefulness of nitrate of amyl in warding off an attack of epilepsy when given as soon as the least suspicion of an aura arises suggests the use of a rapidly acting nitrate not only before, but during the convulsion.

In the New York *Medical Journal* of July 29th, Bates reports the successful employment of nitro-glycerine in twelve cases of epileptic convulsions. In one case in which the patient was totally unconscious with marked muscular movement, a hypodermic injection of one one-hundredth of a grain of nitro-glycerine was given, and before the needle could be withdrawn total relaxation took place, consciousness returned, and the patient called for a drink of water. In one case only was a second dose required. In all the cases the use of the drug was followed by prompt return to consciousness, the patients recovered without the usual fatigue and general demoralization, and the after-effects of the attack were markedly lessened. The writer does not claim for the method that it is curative, but that it shortens the attack, saves fatigue, and has some influence upon the frequency of the attacks.

LOCAL CATALEPSY.

UNDER this title Mitchell describes [1] a curious group of symptoms, observed in a young woman seventeen years old of excellent history and general health.

In December, 1891, she several times dropped her school books from the left hand as if it were tired and suddenly grown weak.

"In April, 1892, on the ulnar surface of the third, and on the adjacent side of the little finger of the left hand, there appeared sundry small blisters or blebs containing serum, which caused some itching and came and went several times. In July, of the same year, she received a slight cut with a knife at the root of the left thumb. There was a good deal of suppuration, and the wound healed slowly. All the fingers then gradually became stiff, and have so remained ever since."

There was no muscular wasting of the hand, but a curious cataleptic condition ensued. The hand was held "with the wrist half extended, all the fingers in semi-flexion, the little finger slightly adducted on the palmar surface of the third finger, the thumb in close contact with the palmar surface of the index finger, and all rigid." There was slight muscular tremor in the forearm and hand. Voluntary motion of the wrist was possible, but not of the fingers. Passive motion was easy at first, but soon became difficult and after a few movements the fingers would become quite rigid and remain for many minutes exactly as placed. There were occasional automatic changes in the position of the fingers.

The sense of pain was lost in the whole left hand as high as the annular ligament, where it suddenly became acute again. Below this a slight pin-prick did not bleed; there was no sense of touch, localization, or temperature change. There was no tenderness over the nerve tracks in the arm, with the single exception of a minute area of pressure-pain in the middle of the flexor surface of the wrist, just above the annular ligament.

In every other way the patient was well and all the bodily functions normal. The rigid condition of the hand persisted during sound sleep. There was no evidence of any neuritis or degenerative nerve change. The author considered it of a hysterical nature in spite of the absence of other manifestations.

[1] American Journal of the Medical Sciences, August, 1893.

THE VOMITING OF PREGNANCY.

AT the last meeting of the London Obstetrical Society, Giles [1] reported the analysis of three hundred cases of pregnancy in reference to the occurrence of vomiting. He found that only about one-third of pregnant women were free from vomiting throughout their pregnancy; that the sickness began in seventy per cent. of cases in the first month, while in ten per cent., it began in the last three months. The sickness was least frequent in women between the ages of twenty and twenty-five, while ninety per cent. of primiparæ over twenty-five suffered from vomiting. There was less sickness during the third pregnancy than in others. Sickness during the first third of the pregnancy was thirteen per cent. more common among primiparæ than multiparæ. Women who habitually menstruated painlessly and scantily, suffered less than others, the degree of pain being a more important factor than the amount of blood lost.

The observation that the third child of a mother is usually the strongest is of interest in connection with the author's statement that vomiting was least frequent during that pregnancy.

He looked upon vomiting as a manifestation of nervous instability, and so dependent on the interaction of three main factors: (1) The increased nervous irritability of pregnancy; (2) a local source of irritation; (3) a ready efferent channel for nervous energy (the vagi).

OBITUARY. — SETH ROGERS, M.D.

DR. SETH ROGERS died August 6, 1893. He was born in Danby, Vt., February 13, 1823. The youngest of twelve children, a prosperous farmer's son, and possessing the conscience of his Quaker parentage, he earned, as clerk in a store, in spite of delicate health, the means for the medical education which was the dream of his early life. He studied medicine at the University of New York and in Castleton, Vt., where he graduated. After two years' practice in Worcester he went to Europe, in 1852, for sixteen months, to make up the deficiencies in his training, of which he was over-conscious, working for the most part in Paris with Trousseau and Valleix. He joined the Massachusetts Medical Society in 1855, and continued the practice of his profession in Worcester until 1862, except for a voyage to South America for his health in 1858.

In 1862 he became surgeon of Colonel Higginson's negro regiment, the First South Carolina Volunteers. But after

a year of devoted service, his health compelled him to give up active medical duties altogether. Four years of outdoor life in Pomfret, Conn., on a farm, where he went, as he thought, to die, brought sufficient restoration of health for him to establish a winter practice in Florida for thirteen years. After 1882 he limited his professional work to the care of patients in his own house in Pomfret and to consultations with his colleagues.

Dr. Rogers early learned to question everything in religion and politics and, later, medicine, and to seek in his over-trained conscience the guide for his life. He naturally grew up an abolitionist. As a physician he was a sincere searcher after the truth, honest, faithful, intelligent, devoted, full of courage and with a rare power of imparting his courage to his patients. He was handicapped all his life by illness which would have disabled most men, and yet he performed a life-work to be proud of.

As a man Dr. Rogers was one of those charming, picturesque characters developed by the stirring events of the long struggle against slavery. An innate nobility of life marked his whole career. Although with him living was a long fight against poverty, he was one of the richest of men and gave away, as few give, of that which is best worth receiving.

Correspondence.

A LAST GLIMPSE OF CHARCOT AT THE SALPÊTRIÈRE.

BOSTON, August 19, 1893.

MR. EDITOR: — The recent death of Prof. Jean M. Charcot, doubtless the most brilliant physician of his day in France, recalls a morning which I had the pleasure of spending with him at the Salpêtrière some three months ago. This hospital which was originally built by Louis XIII for an arsenal, occupies a large tract of ground away at the eastern part of Paris near the Gare d'Orleans. It is so inaccessible from those parts of the city which Americans mostly frequent, that it is rather difficult to get to it at the comparatively early hour at which the distinguished clinician makes his usual visit. On arriving I found that the public clinics were for the time suspended, which may have been on account of the then already manifestly failing health of the teacher. But fortunately, though not appearing in public, he was making his morning visit, and I was directed to his consultation room. Passing through the roomy courts which separate the several buildings, one sees sitting on benches under the great trees, the old women who are favored with a permanent residence in this beautiful spot. Beyond the line of buildings to the right on a little higher level is a shady park of several acres, quite as pretty as any in Paris and open like the courts to the old crones, who with their sewing in hand, wag their tongues with a vigor which makes up for the feeble quality of the product evolved from their weak old brains. Through the open windows are seen the large wards occupied as dormitories by the more chronic and not bed-ridden patients. Such wards have three tiers of beds running their length and are thus a little overcrowded although they are thoroughly comfortable old structures. The wards for the acuter cases, which we shall see later, have only the regulation two rows of beds, and each bed is surrounded by close fitting curtains of cotton, which when drawn, completely isolate the patient. A glimpse of a dining-room with tables laid for the ambulatory patients, discloses a half-glass of red wine at each cover. Altogether, the Salpêtrière strikes us as not at all a bad place, of a bright May morning.

At length we reach the building where Charcot has his consulting room. The patients whom he sees here are, of course, only such as can walk or be readily brought into his presence. He sits before the window, from which the light falls on the faces of the two or three patients who are kept occupying the chairs in front of him. The chief part of the examination is conducted by the middle-aged assistant, who apparently has had previous knowledge of the cases, which Charcot is seeing for the first time. The latter is a striking personality: a large, pale, smooth-shaven face, firm and decided mouth, unusual interocular and frontal breadth, the forehead high, and surmounted by abundant white hair, rising straight and falling backwards. The expression of face is grave and serious, not to say stern; the speech low, and to foreign ears at least, not distinct. Besides the assistants there are perhaps a dozen other visitors in the room — mostly middle-aged men — in fact, about as many as the small space can accomodate with chair room.

The walls of this room are, it is to be feared, calculated to divert the attention of the casual visitor from the cases immediately before us. For on these walls, in fact, almost entirely covering them, is a series of reproductions, photographic and in engraving, of those paintings in which the world's great artists have sought to depict the manifestations of hysteria and hystero-epilepsy. Prominent among them, of course, are pictures of the casting out of devils. Here are seen the demoniac youth from Raphael's Transfiguration and similar figures from the works of other Italian masters and from Rubens. Charcot has evidently made a diligent search through the Italian churches for good pictures embracing this subject, and has got together an astonishing array. By way of comparison with these great painters' conceptions of such phenomena, is placed a photographic copy of the well-known French picture of Charcot himself exhibiting in his clinic a woman with major hysteria.

Besides the more marked representations of the "possessed," we find also in the room pictures of various saints in ecstasy, as St. Francis in the act of receiving the stigmata, St. Cecilia and St. Anthony of Padua, in Murillo's painting at Berlin. In a word, this little room is a museum of hysterical manifestations as they have presented themselves to the observation or, as we must admit, perhaps more generally to the imagination of the masters in art.

But the hour is advancing. The professor will go into a ward to see a patient with reference to the localization of a focal brain lesion and, as we follow thither in his train, we notice, with regret, that while his intellectual strength has shown no abatement, his physical and nervous forces are greatly shattered. His gait is shuffling and unsteady. He walks with difficulty and finally totters to his carriage and is driven away. Can it be that, as has curiously happened to so many prominent medical men, he will fall a victim to one of those diseases to which he has devoted his special, life-long attention? If so, we feel that his self diagnosis will be accurate, however futile his treatment. It is now scarcely three months, and his illustrious career as student and teacher is closed.

C. F. WITHINGTON.

METEOROLOGICAL RECORD,

For the week ending August 12, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,602: under five years of age 1,321; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 846, diarrhœal diseases 643, consumption 238, acute lung diseases 231, diphtheria and croup 71, whooping-cough 35, typhoid fever 31, measles 15, cerebro-spinal meningitis 15, malarial fever 15, scarlet fever 13, erysipelas 7, small-pox 1.

From whooping-cough New York 14, Philadelphia 10, Boston 4, Cincinnati and Cambridge 2 each, Washington, Worcester and Lynn 1 each. From measles New York 10, Philadelphia 4, Fitchburg 1. From malarial fever New York and Washington 6 each, Philadelphia 2, Boston 1. From cerebro-spinal meningitis New York 9, Philadelphia, Worcester, Cambridge, Lynn, New Bedford and Marlborough 1 each. From scarlet fever New York and Milwaukee 3 each, Boston 2, Philadelphia, Taunton and Woburn 1 each. From erysipelas New York 4, Philadelphia 3. From small-pox New York 1.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 12, 1893, TO AUGUST 18, 1893.

By direction of the President, the retirement from active service, this date (August 12, 1893,) by operation of law, of LIEUT.-COL. JOHN H. JANEWAY, deputy surgeon-general, under the provisions of the act of Congress approved June 30, 1892, is announced.

Leave of absence for one month, to take effect when relieved by another medical officer, is granted FIRST-LIEUT. HARLAN E. MCVAY, assistant surgeon, San Carlos, Arizona Territory, with permission to apply for an extension of fifteen days.

Leave of absence for twenty days, to take effect upon the conclusion of his examination for promotion, is granted FIRST-LIEUT. JAMES D. GLENNAN, assistant surgeon, U. S. A.

MAJOR HENRY R. TILTON, surgeon, U. S. A., is granted two months' leave of absence, when relieved from duty at Fort Wayne, Michigan.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 19, 1893.

A. M. MOORE, surgeon, and C. W. RUSH, passed assistant surgeon, placed on retired list.

R. M. KENNEDY, assistant surgeon, promoted to passed assistant surgeon.

J. H. CLARK, medical director; C. H. WHITE, medical inspector, and J. L. NEILSON, surgeon, ordered as members, Medical Examining Board.

M. F. GATES, passed assistant surgeon, from Naval Hospital, Portsmouth, and recorder, Naval Medical Examining Board, September 1, next.

A. R. WENTWORTH, passed assistant surgeon, ordered to Naval Hospital, Portsmouth, N. H.

A. C. GORGAS, medical director; C. A. SIEGFRIED and H. G. BEYER, surgeons, ordered as delegates to the Pan-American Medical Congress.

B. S. MACKIE, and L. G. HENNEBERGER, surgeons, to Naval Academy to examine applicants for admission to Naval Academy.

ELEVENTH INTERNATIONAL MEDICAL CONGRESS.

In consequence of the sanitary condition of several of the European States, which prevents their medical men leaving home, and, following the advice of many of the most prominent scientists, both Italian and foreign, the Executive Committee of the above Congress has decided, by a large majority, to postpone the meeting till April, 1894. The exact date of the inauguration will soon be fixed.

APPOINTMENTS.

CHARLES H. WINN, M.D., of Roxbury, and LAURENCE COLLIER, M.D., of Boston, have been appointed medical examiners on the second Board of Pension Examiners for this district.

RECENT DEATHS.

TIMOTHY STONE PINNEO, M.D., died at Norwalk, Conn., August 9th, aged ninety years. He was one of the oldest alumni of Yale. For a time he practised medicine in the South, but failing health obliged him to abandon this field. He was professor of belles lettres in Marietta College, Ohio, and the author of Pinneo's Grammars.

S. J. F. MILLER, M.D., of Cincinnati, died August 9th, aged fifty-six years. He was at one time surgeon at the Soldiers' Home at Togus, Maine.

JEAN M. CHARCOT, M.D., the distinguished French physician, died at Morvan, France, August 16th, aged sixty-eight years. Of wide clinical experience, he had devoted himself chiefly for the last thirty years to diseases of the nervous system. Of late years he has been especially interested in the scientific study of hypnotism. He was the founder, and till his death, the editor of the *Archives de Neurologie*. He took a large part in the direction of the *Revue de Medecine* and the *Archives de Pathologie Experimentale*. He was a member of the Institute of France, of the Royal Irish Academy, of the Royal Medical Chirurgical Society of London. His best known books are perhaps his "Leçons Cliniques sur les Maladies du Systeme Nerveux," and his "Leçons du Mardi à la Salpêtrière."

BOOKS AND PAMPHLETS RECEIVED.

Bellevue Hospital Medical College of the City of New York. Circular of Information, 1893-94.

Fifteenth Annual Announcement of the St. Louis College of Physicians and Surgeons, Session of 1893-94.

Transactions of the Medical Society of the State of New York for the Year 1893. Published by the Society. 1893.

Thirteenth Annual Announcement of the College of Medicine of the University of Denver, Session of 1893-94. Catalogue of Alumni and of the Matriculates and Graduates of the Session of 1892-93.

Station-list of Officers of the Medical Department and Hospital Stewards of the Hospital Corps, United States Army, July 1, 1893, or at date of last report received at this office. Washington. 1893.

Introduction to the Catalogue of the Collection of Calculi of the Bladder, upwards of One Thousand in Number, Removed by Operation. By Sir Henry Thompson, F.R.C.S., M.B., London. London: J. & A. Churchill. 1893.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XIV.

FROST-BITE AND BURNS.

WE are all quite familiar with the phenomena and appearances of simple exposure to cold. The first effect produced upon the surface is to drive the blood away from it. The part becomes very white; and then, if the exposure to cold is only brief, reaction takes place promptly. The exposed surface becomes very red and congested; burns; glows; tingles; if exposed a little longer, is the seat of intense pain from the returning circulation.

These phenomena, on a small scale, on the surface of the body are due to shrinking of the vessels from the stimulus of the cold. The capillary vessels shrink. The blood recedes. The surface is cooled down. It grows pale. When the cold is removed, the vessels dilate again. The blood returns. The pendulum swings a little further back than the normal limit. Congestion takes place. The skin becomes red and hot; and this sudden afflux of blood is accompanied by pain.

If a large portion of the body is exposed to intense cold for some time, then it follows that a very large portion of the superficial blood must be driven in on the internal organs; and excessive congestion of all the large vessels, and the circulation in the viscera, takes place. This before long affects the brain so that death from cold takes place in a state of coma; stupor being produced by great congestion of the brain; and, if pushed far enough, by serous effusion. We are all familiar with the stories of those who, long exposed to cold, soon give up and desire to rest. They cease to suffer, after a little while, and sink to sleep. It is impossible to resist the inclination to slumber, they lie down and sleep, and die in a state of coma. That is the general effect on the internal organs when the whole surface is exposed.

Now if, on the other hand, the person has only one member exposed to cold, as a foot or a hand, and the cold is not intense enough and long enough to chill the whole body, then that portion which is directly exposed becomes as it is called "frozen." In that case the driving away of the blood from the surface continues so long that it does not return promptly; and alteration also is said to take place in the blood corpuscles themselves, so that they disintegrate. In this case the limb is incapable of repair; and although the part may be again exposed to warmth, and every effort made to produce a return of circulation, yet it sloughs; mortifies; spontaneous amputation takes place; and nature makes a cure by granulation, after the process of ulceration.

In imperfect freezings, where a part is chilled, it is capable of recovery. Where it is chilled so far that it is partially frozen, it is capable of recovery. The circulation returns, and with such violence that the danger subsequently is not in a want of return of the circulation, but in its too rapid return. The part becomes congested too rapidly by the returning blood; hence the familiar rule, after a part has been exposed to cold a long time, that it is not safe to warm it too rapidly; and, as it underwent its starvation of blood, so to speak, by the influence of cold slowly, so you must allow the current to come back slowly, if you want to avoid the next consequence, which is sure to ensue, if it comes back rapidly; and that consequence is intense congestion and inflammation of the part. The danger then of a universal freezing is death from coma and stupor. The danger from a very deep freezing is that the blood will never get back. The corpuscles are altered, and the part dies. The danger of a moderate freezing is that there may be a too rapid reaction and return of the blood. This acts in this way: The part is partially frozen; it is chilled and the blood driven away. The patient goes to the fire or exposes himself to heat. Intense pain and redness is produced; œdema; effusion of blood; loosening off of the cuticle; true inflammatory processes, which end in mortification, suppuration, ulceration, a line of demarcation, and slow repair afterwards.

These modes of injury indicate to us, of course, the modes of treatment; that, if the part is exposed to cold long, the most prudent course is to bring it back to warmth slowly. Apply ice-water, apply snow, and keep it away from heat. Subsequently, when it begins to recover, put on evaporating lotions containing substances like ether, or alcohol, or vinegar, and hold the reaction back. If it can be forced back and allowed to come on in an hour or two, instead of instantly, then the part frequently recovers with a partial inflammation. A partial inflammation causes death of the skin usually; and that gives rise to a very troublesome series of phenomena, but these are not dangerous. Moderate frost-bite if it has been successfully treated, always ends in some death of the skin. This is shown by blistering off of the surface, by the occurrence of subacute eczema, which very frequently follows. That is especially true of moderately frozen ears; in which the ear afterwards becomes the seat of eczematous inflammation for several weeks before it finally recovers.

The same is true of the nose and face and other exposed parts. So on the hands the skin of the fingers may peel off, and the nails may be loosened and some of them drop off, without absolutely freezing through the finger.

Exposure to cold; reaction to be delayed; that is the rule of treatment. Exposed to severe cold with tendency to torpor, the safety of the individual consists in being roused and shaken and driven about and forced to exert himself, to avoid the peril of death.

The spontaneous amputations and sloughings which come on after frost-bites affect most commonly the parts most distant from the centre of the body; the fingers and toes. We see it occasionally occur in this climate on land; and quite frequently in sailors who get the hands and feet frost-bitten by the combined action of the salt water and cold and exposure. These cases are frequently brought to us for treatment in the state of moist gangrene; rapid inflammation followed by gangrene. It is always of the moist variety. It is offensive, soft, sloughing, black, with a distinct line of demarcation forming. It is injudicious to interfere until the line of demarcation has fully formed. It is sometimes questionable whether it is worth while to interfere at all until spontaneous amputation has been pretty well performed; then we can judge whether

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

we can get along with the protruding stump, or whether it is necessary to make a primary amputation back of the injury, and get sound flaps. Whether we do this, depends a good deal on the extent of the frost-bite and the location of the part. For instance, it is extremely important to preserve a thumb as long as possible; and, if we can get off by shortening a little piece of bone and have it recover by granulation, it is better than to amputate high up.

So that in some of these cases it is wiser to wait until spontaneous amputation has taken place down to the bone, then to press back the granulations, scrape them back with the periosteum scraper, saw off the bones high up in the bleeding tissues, allow the granulations to come back over them, and allow the natural processes to go on. In that way we sometimes save important parts.

BURNS AND SCALDS.

Perhaps it has not occurred to you that these are the most frequently fatal and numerous accidents of civil life; and also this other point, which is worth remembering, that more than three-fourths of all the burns and scalds occur in young children. It is natural that it should be so. They are the most careless and most exposed. They go the most about stoves and lamps with their short and light clothing. They are unable to protect themselves after they are burnt. They are much more likely to have a serious burn than an adult because the first impulse of the child on being afire is to throw open the mouth and shriek, and inhale the flame or gas; which they frequently do with fatal result. The shock, also, to these young subjects when burnt is more severe and more fatal than it is with grown persons.

Scalds are not nearly so severe as burns. Burns are produced by fire; scalds by heated fluids, or steam. The species of burns produced, however, by the melting of substances which are denser than water, as for instance, molten lead or molten iron, anything of that kind, are more penetrating and more deep than the burns produced by simple fire, whether of wood or coal. The burns produced by heated metals are the deepest and most severe; the burns produced by fire are the next; the true scalds produced by fluids and gases are much less so. It is rare that a scald, so-called, goes far into the true skin and deeper tissues; but scalds mostly belong to the set of burns which are, what is termed, of the first class. The French authors have divided burns into six classes; but that is quite a needless minuteness of subdivision. Dividing them into three classes is quite sufficient; and practically only two of these are what we have much to do with.

The first is that which destroys the epidermis and does not penetrate the true skin.

The second destroys the epidermis and goes through the true skin, to a greater or less depth, into the cellular tissue or muscles.

The third class are those which go through the muscles, and go down and perhaps even char the bone.

A person, for example, who is epileptic or drunk, and who falls into the fire, or onto a hot stove, may lie unconscious, and have the limb deeply charred, or the third form of burn. The electric-current and the electric-wire burns are always of the third class, if it is in contact long enough with the tissues. The linemen who repair the wires and get burnt are occasionally brought to the hospital; are occasionally burned in the hand from catching hold of the wires; and the wire burns down through the mass of the adductor muscles and burns the bones themselves. That is quite a common accident from the electric current. A similar sort of burn is produced, by a different cause, among the workers in iron; in blasting furnaces, especially in the handling of long rails, that are drawn out of the furnaces in a bright red state, previous to being hammered into shape.

These burns almost invariably extend down to the bone; and so do the burns from the electric current. On the other hand, the patient who is scalded by hot water or steam has the epidermis peeled off, but the true skin is not affected.

The first class of burns does not scar; the second class of burns does; the third produces deep mutilations.

There are three or four things which seem to influence very much the prognosis with regard to a moderately severe burn. The first is the age of the patient. The next is the location of the burn, and the next is the extent of the burn, the extent more than the depth, and for this reason: the shock inflicted upon the system by a scald or a burn, is due to the rapid burning off of the sensitive nerves which supply the skin. The skin being the organ of touch, is enormously endowed with nerves. The filaments terminate there; and they are the organs of a very acute sensibility. A burn chars off the surface; inflicts shock and intense pain; and destroys their function. Now the more skin that is burned the greater the shock. The shock is greater over the larger extent of skin, in a burn of that kind, then in the deep burn which goes far into the tissues toward the bone. This is familiar in regard to the pain of surgical operations. The patient suffers intensely while the skin is being cut; much less when the muscles or deeper tissues are being divided. The shock of a burn depends upon the amount of skin involved; and therefore it is that the extent of a burn is of more consequence in the prognosis of the patient than the depth of it.

The location also is important. The most dangerous place to be burned is the front wall of the abdomen; the next, about the chest, and third, about the scalp. The limbs, much less danger.

The age of the patient you may reasonably suppose would make a good deal of difference in the prognosis, as it would in any class of injuries. Repair is more difficult in the old than in the young, as would naturally be supposed to be the case.

The effect of burning off the skin, or flaying the patient, so to speak, over a considerable surface, say a foot square or more, the effect of burning off so large a surface is certainly to inflict a most terrible shock to the nervous system from the pain produced by the sensitive nervous filaments, hundreds of which are destroyed, and also to produce very serious consequences on the internal organs of the body by the loss of the skin; the interruption of the functions of the skin as an excreting organ. A large burn produces in the internal organs precisely analogous changes to those produced by that acute inflammation of the skin with discoloration which we call scarlet fever. The subsequent consequences are very similar. In consequence of the loss of function of the skin, the power of perspiration and excretion is lost. The excreting organs in the interior of the body have then to do all this additional work. The consequence is congestion of the

kidneys to a very marked degree; congestion of the mucous membrane of the alimentary canal also in large burns; and in severe burns there will be very likely albuminuria, and ulcerations in the mucous membrane of the bowels. It, of course, would also be probable, and is the case, that in severe burns about the face and scalp the delicate structures inside the skull are liable to be congested, and meningitis, or serous effusion is liable to follow within the head itself. In addition to all this, if a burn happens to occur on the front of the abdomen where the walls are very thin, the immediate consequence is liable to be the occurrence of a mild degree of peritonitis produced by the irritation of the burn, with serous effusion or ascites inside the abdominal cavity; or, also, as is occasionally seen in large burns about the thorax, the pleural cavity becomes filled with fluid, and there is pleurisy under the seat of the burn. These facts must make it plain why it is that the location of the burn is of so much importance, and the extent of the burn is of so much importance. I do not care to add the depth of the burn as regards the prognosis and the symptoms. We agree about the depth in this way, that it is going to produce a serious and hard scar; but it is not so dangerous to life if a burn goes in several inches into the flesh, as if a superficial burn spreads over several feet of surface on the abdomen, or thorax, or upon the thigh.

There are three periods of danger in a burn. The first is immediate and is due to the shock, which occasionally produces fatal collapse. The next is due to the internal congestions and inflammations with fever, which are liable to follow immediately from the destruction of the skin; and the third period of danger is, if these have been passed through, the long-continued suppuration which follows the repair of the burnt surface; throwing the patient very much into the condition of hectic we see so often in the wasting suppuration of the joints and of the spine. Shock, then, first; then a period of inflammation; and then the period of exhausting suppuration.

The most marked and curious pathological result on the internal organs from the burn is the effect on certain portions of the mucous membrane of the alimentary canal; and, for some unknown reason, these troubles seem to expend themselves upon a certain tract, and that tract is almost invariably the duodenum, just below the pylorus, where circular, punched-out, depressed ulcerations, with hæmorrhage, are common. It is a thing to be looked out for. The statistics from autopsies show that ten to twelve per cent. have these ulcers; and when they occur they are the cause, occasionally, of a fatal termination of the case. The symptoms are not very marked. The diagnostic symptoms would be diarrhœa and bloody stools, and, perhaps also, vomiting, though not always; great pain or tenderness over the duodenal region are said not to occur to any very great extent. They are not marked symptoms. The nausea, diarrhœa, bloody stools are the signs of duodenal ulcer. They indicate to us, of course, that our treatment should be directed to do what we can to allay the excitability of the mucous membrane and to allow it to heal. We should try then, by simple treatment, to allay irritation by opium; to check diarrhœa by the same means; to give only those kinds of food which would leave the least possible sediment to pass over the irritated bowel; to choose that kind of food that would be digested by the stomach alone rather than in the duodenum; and by such treatment as this, endeavor to promote the healing of the ulcer. Perhaps, also, we may be able to prolong the patient's life, and give them time to heal, by rectal nutrition; by enemata and stimulants administered by the rectum.

Acute congestion of the kidneys followed by albuminuria will have to be treated as it would in other cases of commencing Bright's disease, or in other cases of congestion of the kidneys, by endeavoring to see as far as possible that the function of the skin, where it has not been destroyed, be kept up by promoting sweating; by warmth applied to the surface; and by giving diluent drinks; possibly, in bad cases, applying cups over the kidneys.

To recapitulate, we say when a patient is burned over a large surface he is in much greater danger than if burned deeply over a small surface. The three periods of danger are: first, immediately from shock and collapse; next, from inflammation and congestions internally; and finally, from suppuration.

What are the phenomena and appearances of a burn when first received? The pain, we all know, is intense, terrible, demoralizing. Directly after this follows a period of partial collapse; that is, if the burn is severe, the temperature of the body falls and the patient complains of cold; is chilly, shivers. After this has gone by the pain still continues; and a period of acute heat and inflammation gradually comes on, with restlessness and fever, and perhaps some signs of trouble inside the cavities of the body.

The shortest way to stop the pain of a moderate burn upon the surface is to get it covered in from the external air as speedily as possible, and restored to the normal temperature of the body, in other words, warmth and occlusion from the air are the means of checking the pain, and checking the shock. You will see why this must be so. The skin is burnt off. These terribly sensitive nerves are all exposed to a different temperature and they are in great pain from this exposure. There is no cure for it but to make some sort of an artificial skin, which shall cover them in from the air, and restore the temperature and keep them still. That is one treatment which is perhaps the earliest and most important of all. Nothing else does any good until this is done. But other methods of treatment also are important. It is important to give stimulants, and to give opium in the first stages of this pain and shock. Opium should be given gradually and cautiously, until the patient is quiet and easy; and stimulants freely in the period of collapse. Then the patient should be kept warm, and the burnt surface covered in from the air. This expresses the very simple rules of the earlier treatment of burns. In carrying them out some little judgment is necessary. Supposing, for instance, the patient is a child, who has fallen partially, that is the legs or arms or some part of the body, into boiling water. The clothing is on. The child is scalded through and through under the clothes; and the cuticle is all loosened and ready to peel off. If we can preserve that cuticle without peeling off, that is the best covering for the burn itself; and if that is stripped off, it is a great loss to the patient, increasing the suffering and preventing repair. In taking off the clothing we are apt to destroy all that cuticle; and hence comes the important rule that no clothing should be drawn off from a burned patient; but everything should be sacrificed without consideration as to value; slit down with sharp scissors, and

laid off so that the cuticle may be left upon the part. That is a very important point.

Next to that, the burn being seen, what shall be applied? Anything that will cover it in from the air. According to the degree of burn various substances may be used. If we accidentally get the hand for a moment upon a hot stove and withdraw it and find it reddened and vesicated over a small surface without the epidermis being actually denuded, that form of burn will be relieved, as regards pain, by sprinkling it over with common table salt. That is the common expedient of cooks. They are being burned here and there all the time. They wet the part and cover it instantly with salt, and the pain is relieved. A similar treatment, a very good one, is to tie the part up at once in dry cotton batting; and cover it in from the air in that way. That also relieves the pain to a very great degree.

For a person with burns so severe that the skin is peeled up, and a bubble of fluid is formed under it, the edge is denuded and serum is flowing out, in that case, the salt is not applicable; neither is the cotton batting. The best treatment for that is to dust the part over with flour, and allow a species of artificial scab to form over the part, which is then loosely bandaged. Any dry or innocuous powder, like flour, or powdered starch, or rice powder, is perfectly good to cover temporarily a burn. It shuts it in from the air, and makes a very good temporary dressing.

Again, another class of substances which exclude the air almost better than anything else are those which contain grease, or fat; any form which is free from salt, and which is not rancid will do for this purpose. The simplest and most applicable, usually, is olive oil. Castor oil is equally good. Castor oil is an irritant to the mucous membrane of the bowels, but not an irritant to a granulating surface. It is innocuous, smooth, thick, holds its place well. The fat of mutton is good. So are the simpler salves, as rose-water ointment, or benzoate of zinc ointment. These common remedies are generally used first; and nothing affords the relief that the rapid pouring on of some soft, soothing form of oil or grease does upon the surface. The pain is allayed very soon, and the part is protected from changes of temperature and from the irritation of the air. One of the common remedies used, which is very good and used largely, is what is called carron oil, made of boiled linseed oil and lime water. This makes a nice covering; soothing and cooling for a burn. The only objection is the odor; which in burns about the face is very disagreeable from the smell of the linseed oil. This can be overcome, to a certain degree, by the use of some simple perfume. In all burns about the parts distant from the nose it is as good as anything you can possibly put on.

An artificial cuticle made in any way is good for large and deep burns. Sometimes it is made by dissolving gum arabic in water with molasses; sometimes from various forms of gluten; anything which will form a scab on the surface in drying. It must be unirritating, and it must dry in the form of a scab. Now, this is an excellent application, makes the patient perfectly comfortable, and supplies the place of the lost skin. Unfortunately it is apt not to be permanent; and has occasionally to be renewed. The reason that it is not permanent is twofold: in the first place from the slight movements of the patient; and in the next place, every burn in this class of burns pours out serum or pus, and these lift up and burrow through the artificial cuticle, and it requires either to be taken off, or patched, occasionally.

So much for the earlier treatment of these burns. As for the later treatment, then we come to the period of suppuration, which is a peculiar and very tiresome one. The ulcerations of burns are peculiar in this way that the granulations are very large and florid and sensitive. It seems as if nature was making an extra effort to repair the burn, and instead of granulating quietly, as the ordinary ulcer on the leg will do, when not inflamed, this turns out masses of papillæ-like growths, which are made up of little masses of cells with a vessel and nerve in them; active granulations which occasionally become watery and œdematous and swollen, and bleed easily at the slightest touch, and are very sensitive. They are what we call in the ordinary ulcer exuberant granulations, or "proud flesh." This is the common form of healing of a burn; and it gives a great deal of trouble in taking care of it. It overgrows, so to speak, in repair. It rises beyond the level of the original parts. It is extremely sensitive, and it secretes a great deal of pus.

The oily applications, or the artificial cuticle, are generally the best things for this sort of case also, to allay the irritation. We should not, I think, look upon the pus which is developed upon these surfaces as an unmixed evil. It is a good covering; a poultice to the part; shields it from the air, and enables healing to take place beneath. You no doubt are familiar with the fact that healing by granulation goes on rapidly under the suppurating fluid, frequently; and although the suppuration is excessive and is to be cleansed well, it is a question whether cleansing it too often does not interfere with the process of healing. At this later stage, when suppuration is going on so rapidly; it is difficult to do much with the artificial cuticles; and we have to trust to what are called open dressings, and to change them. To change them often is productive to the patient of terrible shock and terrible suffering; and this is especially the case with children, who, of course, are unwilling to reason, cannot reason on the treatment which is being pursued, but dread the dressing as they do almost a sentence to be flogged; and scream and cry and exhaust themselves in anticipation of it, whenever it is about to take place; therefore it has been found, that frequently, in these burns it is not best to dress them too often; and instead of being kept in a state of most scrupulous cleanliness, they had better be dressed once in forty-eight hours, rather than in twenty-four, since the suffering is less, the shock is less, and the patient gets well quicker.

Nowadays repeated attempts, and sometimes successful ones, have been made to apply antiseptic methods to the subsequent treatment of burns; and so far as they can be used they are extremely useful, but the difficulty is in dressing often; in not allaying pain; and in destroying too much, sometimes, the covering of suppuration. The various gauzes are not very well adapted to apply to the granulating surfaces of a burn, because the fine web of the gauze catches on the smaller granulations and is washed off by suppuration; or, if it sticks, too great pain occurs in detaching it. On the whole, probably, these cases get along about as well with the treatment by the oily applications; but when we come to a much later date, when the acuteness of the burn has largely subsided, and when we have left a chronic indolent ulcer of large extent, no

very sensitive, as it is not in these later stages, which cannot heal, then the method of skin grafting, and especially the more modern method known as Thiersch's, by laying on thin slices of cuticle and protecting the whole by a water-proof covering of thin rubber, is extremely useful and extremely comfortable; and this treatment may be used in the latter stages of burns with great success.

When called to a burn, we are to allay pain, and give stimulants, at once. Be excessively careful how the clothing is got off. If a child is burned badly, put it to bed under a cradle; and apply the dressing you need. Apply warmth at once. Keep up the bodily temperature; for, strange as it may seem, while the first suffering is from the intense heat of the burn, the subsequent suffering is from collapse and coldness; and you want to restore the circulation and the natural warmth of the body. Give opium and stimulants and warmth. Get the clothing off carefully, and dress the burn temporarily, at any rate, with the first bland agent which is at hand, which will cover it in from the air. Subsequent dressings are to be made infrequently. Watch for complications of the brain, or chest, or abdomen; and treat them as well as you can; and, in the later stages, when the exhausting period of suppuration comes on, the patient must be treated precisely as in other cases of hectic; and tonics, stimulants, etc., used, to try to make up for the great waste of this suppurative process.

Unfortunately this is not all that is liable to follow. Unfortunately this exuberant granulation of the burn, this peculiar form of ulceration and reluctant healing, is followed by an unusual deposition in the scar of elastic or fibrous tissue, and by intense contractions; and that is the thing you must guard against all the time. The fingers, the elbow-joint, the knees, the neck, all are the seat of disastrous, contracting cicatrices. The same condition also affects burns about the orifices of the body; the mouth, or nose, or vagina; the mouth and the nose especially, which are frequently burned, subsequently heal in such a way that the mouth may be drawn down into a puckering ring where it is impossible to use the lips well, or the nose contract so that the patient cannot breathe through it with comfort. Also we must be on our guard lest contiguous surfaces contract adhesions and grow together. This is especially true of the fingers; which, if they happen to be badly scalded and lose their cuticle, the whole cuticle coming off like a glove, subsequently will heal with adhesions across, and tie the fingers together in a web, if we are not extremely careful. This is doubly true of a little child, where they are intolerant of treatment, and cannot understand what we are trying to do. It is of vast importance, in treating burns of the hands and of parts contiguous, that they should be kept strenuously open to prevent subsequent contractions and adhesions between the fingers. To prevent the contraction of parts, pulling up of the knee, etc., we have to have recourse to mechanical means, and apply splints to keep the parts well straightened, while healing is going on. On the hand, for instance, a dorsal splint and the fingers strapped back as firmly as possible, if there is danger of contraction; or an outside splint may be made of tin, to keep the arm straightened at the elbow.

If the skin is badly burned in the neck, the consequence is, first, pulling on the chin; then on the angles of the mouth; then on the eyes; so that, in some extreme cases, the patient has the chin drawn down nearly to the sternum; cannot close the mouth; cannot close the eyes; and is, of course, a horrible object, and very miserable for the rest of his life.

Here I would like to call your attention to a treatment, which has been successfully used in Vienna, and some other places, in cases of bad burns in the state of cicatrization, by hot water; keeping the part, if it is a limb, constantly immersed in hot water, kept at the temperature of the body. Baths have been contrived for this, with a little grating on which the patient can lie, and the part be nicely submerged; or else a little tank has been constructed in which the arm can lie, and the temperature be kept steady; and there is a little feeder of warm water to supply the waste by evaporation. No dressing is needed on the burn whatever, except the water. The burn heals in the water nicely; and it is claimed that it heals with a soft and supple scar. This treatment certainly is worth following out.

Provided we are left, after all our efforts, with distortions and cicatrices, what can be done? We have spoken of the means of skin grafting to enable a large ulcerated surface to heal. I think the method of Thiersch is the best. Now you must bear in mind that skin grafting by taking minute points as large as a grain of wheat from the epidermis has been used fifteen or twenty years, and is successful, but slow. Thiersch's method is more rapid. The cicatrices, however, after they have contracted, have to be treated in another way; and that is by section, and transplantation of flaps of skin, if possible, into the diseased surface. This sometimes can be done with great advantage in the palm; especially in the elbow; care being taken to cut out all the cicatrix, and match the new flap to skin which is sound. It is extremely difficult to make cicatricial tissue unite to sound skin without suppuration, and without giving way, and without a new ulceration; so that, if possible, a part must be selected where the whole scar is cut out, and a nice bed of sound skin left all around; and a large flap of sound skin taken and turned in, with a nutritive pedicle left. I would emphasize this point, that you must cut away all of the scar; and, also, that when you want to make a flap to turn in, you must make it a great deal larger than to fit the bare spot, for it shrinks to one-half the size.

A CASE OF CALCULOUS PYELITIS, WITH COMPLETE SUPPRESSION OF URINE FOR SEVEN DAYS; RELIEVED BY OPERATION.[1]

BY A. T. CABOT, A.M., M.D.,
Surgeon to the Massachusetts General Hospital.

In cases of calculous pyelitis we may have suppression of urine brought about in several ways.

It may be induced by the presence and irritation of the calculi in the pelves of the kidneys, without any stoppage of the ureters. Kidneys which contain stones often undergo inflammatory changes which gradually disable them, and thus a diminution and final cessation of function may be brought about. Even when the pathological changes have not progressed very far, such kidneys may not be able to bear any extra work that is put upon them. In one calculous patient, I

[1] Read before the American Association of Genito-Urinary Surgeons.

have seen immediate suppression follow an operation for appendicitis, with moderate peritonitis. The kidneys showed interstitial changes which were not considerable, and yet their power for work had been so diminished that they were overcome by the ether, and by the increased elimination required by the absorption of inflammatory products from the wound and from the peritoneum. Although the calices were occupied by many stones in this case, there was no obstruction to the flow of the urine.

The way, however, in which calculi more commonly cause suppression, is by obstructing, or occluding the ureters. The condition under which this occurs, and the mechanism by which the suppression is induced may vary considerably, as follows:

(1) Both ureters may be simultaneously obstructed.

(2) One kidney having been previously destroyed or disabled, the ureter leading from the remaining kidney may be stopped.

(3) One ureter only being occluded, the irritation of the stone may by some inhibitory effect lead to a cessation of function in both kidneys.

There may be some doubt whether the case that I am about to report belongs in the first or second category. From the observations I was able to make, it seemed probable that the right kidney was more seriously affected than the left, that its ureter had been blocked for a longer time, and that finally it was the obstruction of the left ureter that caused the total suppression.

E. A. P., a strong man of sixty, was seen by me in consultation with Dr. G. K. Sabine of Brookline, Mass., on December 12, 1892.

His previous ailments had not made a great impression on him, and it was therefore difficult to be sure of his accuracy in his observation of his symptoms. His history was as follows:

He had always been subject to rheumatism. Seven years ago he had an attack of renal colic in the left kidney and passed two stones. He then was well until two years ago, when he had an attack of pain in the right side and passed a stone that was larger than the previous ones. The pain in this attack was thought to be due to rheumatism, and was not so severe as is usual in renal colic, so that its origin was not suspected until the stone was passed.

He was then free from trouble until November, 1892. Early in that month he had some twinges of pain in the right side, which were thought to be due to rheumatism. They passed off. Then a similar pain came in the left side on the 19th of November. He sent for Dr. Sabine on the following day. The pain in this attack was not severe, but was recognized as similar to that which he had had two years before, when he passed a stone. He gradually got better, and on December 5th he went to his business in town, but was seized while there with such an acute pain in the back that he went directly home again. This attack was so severe as to throw him into a profuse perspiration, and the pain was felt through the abdomen as well as in the back; and was distinctly referred to the left side.

On December 6th it was noticed that he was not passing any urine. The anuria continued through the 7th, 8th and 9th. On the latter day a catheter was passed, but only a drachm of turbid urine was obtained. From that time there was no water, up to the time that I saw him on the evening of December 12th.

At my examination he looked quiet and easy, not at all like a sick man; he had no nausea, no headache, no drowsiness, — in fact, he said he felt perfectly well. I made an examination, but could detect nothing, either in the abdominal or lumbar region. There was no tenderness anywhere, even to forcible pressure. I advised that he should take considerable water, should have a mustard poultice over the kidneys, and that sugar of milk should be administered freely through the night.

I saw him again the following day. He had passed no urine. Dr. Sabine thought he was a little more dull. His tongue was very dry, but he had no pain, except that occasioned by a slight flatulence. His pulse was 76 and of fair strength. He said that he had some relish for food, and no nausea. I again examined his abdomen, and thought there was a little more resistance in the right renal region than in the left. He also at one time thought that he felt a tenderness there during my examination. The rectal examination showed a prostate of moderate size, but nothing above the prostate, either of tenderness or hardness, in the region of the ureter.

The evidence seemed to show that the function of the kidneys had been interfered with by some mechanical obstruction, probably a stone, and an operation was advised for its removal.

In view of the total suppression of urine, accompanying the attack of pain in the left side, it was thought probable that the right kidney had previously been rendered useless, either by destruction of its secreting portion, or by blocking of its ureter, and that now a calculus had shut off the secretion of the remaining kidney. There was no evidence to indicate the seat of the calculus, and it was designed to open the abdomen by a median incision, to examine both kidneys and their ureters, and then to proceed, in the best way possible, to the correction of whatever condition was found. This plan was agreed to, and the patient having been removed to a private hospital, the operation was performed on the morning of December 14th, between seven and eight days after the establishment of complete anuria.

On the morning of the operation he had begun to show evidence of constitutional disturbance. The pulse and temperature had risen decidedly, and there was some commencing mental hebetude.

The operation was done under ether. The hand was introduced into the abdomen through a median incision between the umbilicus and pubes. The right kidney was felt to be enlarged to perhaps three times the normal size; its surface was irregular and divided into large lobes. Careful palpation of the ureter was difficult, on account of the abundance of fat in the post-peritoneal tissues, but no hardness suggesting a stone could be felt anywhere in that pelvis or ureter. The left kidney was of normal size, and its pelvis was not distended with fluid. The ureter on this side was followed down with great care, from the kidney to the bladder, but nothing like a stone could be detected. The bladder was contracted in the pelvis. The condition of things thus far confirmed the previous opinion, that the right kidney was previously disabled, and it also strengthened the belief that the stone which caused the final suppression was blocking the left kidney.

With the object of more carefully palpating this organ, which was deeply buried in fat, I made an ob-

lique incision in the left loin and uncovered that kidney. With one hand in the abdomen and the other in the wound in the loin, very careful search of the pelvis of the kidney and of the upper part of the ureter was possible, but the result was negative.

The operation was now abandoned, as there was no light by which further action could be guided, and the abdomen was closed; the wound in the loin being drained and partly closed. The opinion was expressed to the friends that possibly our thorough manipulation would be found to have dislodged the obstructing body, but that failing in this we had accomplished nothing.

The patient recovered from the ether well, and about three hours later, when I saw him, there was a slight escape of urine through the urethra, and on passing the catheter, thirty-seven ounces of light-colored urine were drawn. This flow continued, so that partly by the natural efforts and partly by catheter, two gallons of urine were obtained in the first twenty-four hours. In the second twenty-four hours, the amount fell to about five quarts, and after that there was a steady, gradual diminution, until the daily amount had reached the neighborhood of seventy ounces, at which it held.

Convalescence was satisfactory, and about a fortnight after the operation I washed out the bladder with a litholapaxy pump, obtaining a few grains of calcareous matter, thus completing the evidence that the ureter had been stopped by a calculus, which had been displaced by my manipulations.

In this case the condition of the left kidney is to me of especial interest. The fact that the pelvis was not distended with urine seems to show that the function of this organ was stopped at once by an inhibitory action due to the irritation of the calculus in that ureter, and was not due wholly to the obstruction to the flow of urine and to the back pressure exercised by this obstruction. This cessation of the secretion of urine in this kidney would explain the short duration of the pain when this ureter was blocked. Had the urine continued to be excreted, the internal pressure in the kidney would probably have caused a longer duration of pain, and it would have been much more severe in character.

A laparotomy for the determination of the site of a calculus in the ureter is no new thing, and its importance has been alluded to by me in an article upon "The Surgery of the Ureter," read before this Association, and published in the *American Journal of the Medical Sciences*, for January, 1892. In cases previously reported, this exploration succeeded in locating the position of the stone and in making its removal possible.

The case which I have reported illustrates another way in which this operation may be of use, by enabling us to assist the passage of the stone along the ureter, and thus to relieve the dangerous suppression caused by its presence there. The calcareous matter pumped from the bladder in my case, was so small in amount that, put together in the form of a consistent stone, it would not make a mass which one would expect to recognize by palpation through the walls of a ureter surrounded by thick layers of fat, as they were in this instance. The accidental efficacy of the kneading which was given to the kidney and ureter during my thorough examination of them, would suggest the importance of this massage being systematically carried out in a similar case, where a calculus could not be discovered.

Shortly after the occurrence of my case, I found in the *Annales des Maladies des Organes Genito-Urinaires* for January, 1892, the report of a case by M. Duffau-Lagarosse, which in many respects would seem to be very similar to the case which I have reported.

The patient, a man of fifty-nine, had not urinated for eight days. Three weeks before he had been seized, without appreciable cause, with a severe pain in the right lumbar region. This was accompanied by vomiting and scanty and bloody urine. After this there were fifteen days of comfort, and then the complete anuria appeared.

A calculus being suspected, an incision was made into the right kidney through the loin. Nothing was found, and the patient died the following day. At the autopsy the left kidney was found to be completely destroyed, while the right ureter was stopped by a calculus of the size of a grain of rice, which was lodged in the lower part of the canal.

The reporter draws two conclusions, first, that anuria induced by reflex action is a rarity; and, second, that the diagnosis of the seat of the calculus is very difficult, and indeed impossible.

In this case the small size of the calculus and its lodgement in the lower part of the canal, would probably have made its discovery difficult or impossible. Had the kidney continued to secrete urine behind so small a stone, its passage onward into the bladder would probably have been assured. In the absence of this pressure from behind, it would seem as if this were distinctly a case in which a median laparotomy and massage of the ureter from above downward might have accomplished the escape of the calculus and the recovery of the patient.

I cite this case simply to show that this condition is one which we must be on the lookout for.

The subsequent history of the case I have reported, is interesting in some particulars.

Not long after the patient had gone from the hospital, while he was moving about the house freely, he had another attack of discomfort in the left side of the abdomen, accompanied by a chill and high temperature. I saw him after this had persisted for a good many hours, and found him passing an abundant quantity of water, but still suffering from discomfort through the lower part of the abdomen on the left. Careful examination detected nothing abnormal in that region.

Remembering the experience of the previous attack, I made considerable massage through the abdominal wall, down along the course of the ureter and as deeply into the pelvis as I could reach. When I saw him a day or two later, he told me that from the time of my examination he was comparatively comfortable, and had no more of that seriously uncomfortable pain from that time. A week or two later a stone was passed that was decidedly larger than the calculous bits that were obtained by pumping after the operation. I have not seen the patient since, but have heard that he has had still another attack of pain, with again the passage of a stone.

The conclusions which I should draw from the experience gained in this case, and by a study of the literature that I have made, are:

(1) That in a calculous patient, or in a patient with a distinct attack of renal colic, the suppression of urine should be regarded as directly due to the stone,

and that in the majority of cases, both kidneys will be found to be disabled; for the cessation of the function of a healthy kidney, due to the irritation of a stone in the opposite ureter, must be very rare.

(2) These cases should be treated by operation as soon as it is evident that the function of the kidney has come to a standstill, as there is little chance of the stone being pushed along the ureter when the kidney is no longer excreting urine behind it.

(3) In the absence of any evidence as to the location of the calculus, the first step in such an operation should be a median laparotomy, with the hope of discovering the whereabouts of the calculus, in order to proceed intelligently for its removal.

(4) If by this examination no calculus can be found, so that further operative procedure cannot be decided upon, a steady massage of the pelves of the kidneys, and of the ureters, from above downward, should be practised, in the hope of dislodging or breaking up a small calculus, if such exists.

LONG-CONTINUED BLADDER DRAINAGE.[1]

BY PAUL THORNDIKE, M.D., BOSTON.

THE employment of absolute rest has long been recognized as an essential in the treatment of most forms of inflammation which affect the genito-urinary organs and especially the bladder, it being a comparatively common procedure to drain the latter organ for a few days either through the urethra or perineum, in order to obtain for it as complete a rest as possible under certain conditions. The long continuance of such drainage is less often carried out.

The writer offers these remarks on a few cases of long-continued drainage in the hope that they may serve as a basis for such a discussion as will demonstrate the views which different gentlemen present may hold on this subject.

There are unquestionably cases of prostatic and vesical disease of obstructive origin where the condition of the bladder demands drainage as a means of relief. In this way is provided rest from the bladder's irritable contractions and also from the pain and discomfort which catheterization frequently repeated for long periods of time, almost inevitably induces. Such cases are common enough, and the relief obtained by proper drainage is prompt and sufficient. Drainage may be afforded through a catheter tied into the bladder and removed only to be cleaned, or through a perineal wound, with or without a drainage-tube. In many cases the catheter drainage suffices, as was true in a case to which I will ask your attention in a moment; and in others the perineal outlet is preferable, because the operation is rendered necessary for diagnostic or therapeutic purposes aside from the question of drainage, or because the mental condition of the patient is such as to render it very difficult to keep a catheter of any sort in his urethra. It is the writer's belief that perineal drainage is a more effective way of keeping the bladder empty than drainage through the urethra can be, and should be the method chosen if the conditions are such as to warrant its use. That these methods of drainage may often be continued for a long time with the greatest advantage to the patient is unquestionably true, and that a permanent drainage of the bladder adds many years of comparative comfort to many lives is doubtless also true. The following case well illustrates the efficiency of long-continued drainage through a catheter in the urethra:

C. C., a man of sixty-six years, came under the care of Dr. Watson and myself with an obstructive prostatic hypertrophy of four years' standing. Had had an overflow bladder for months. In spite of the utmost care [he was put to bed and his bladder emptied with a soft catheter, a week being employed in completely emptying the organ] he developed a subacute cystitis, with coated tongue, high temperature, restlessness, anxiety, marked lassitude, etc. Did not improve. Became worse, and at the end of a week or ten days was critically ill. Specific gravity of urine 1,009. Soft rubber catheter tied into bladder and left in for three weeks, during which time patient was kept in bed and the catheter was removed only for a few moments at a time to be cleaned. On the second day improvement began. Temperature became normal, and at the end of two and a half weeks the urine which had been full of pus became clear, with specific gravity 1,017; and in three weeks patient was up and began a regular catheter life. Since then he has remained well. It is the writer's firm belief that this patient would have died if the continuous drainage had not been instituted.

Let me make brief mention of two other cases of Dr. Watson's and my own, where the drainage was through the perineum, and was kept up for a much longer time.

G. T., age sixty-seven years, had had an obstructive prostatic hypertrophy for seven or eight years, and an overflow bladder for two months before beginning to use a catheter. Had an attack of retention which he relieved for himself by the passage of a catheter. This was followed by loss of voluntary urination and a subacute cystitis. Specific gravity 1,009; trace of albumen; no casts found. For four years he did well with regular catheterization. Then began to have pains along course of urethra and frequent and painful micturition, which became unbearable; and patient's physical condition became very bad. Also had recurrent attacks of epididymitis. Operation, November, 1891. Perineal section for purposes of exploring and draining bladder, which was found coated with phosphatic deposit. This was curetted thoroughly and soft catheter tied in. For two and a half months it was left in continuously, being removed only for cleaning. Then it was provided with a stopcock, and has been worn constantly for the nineteen months since the operation. Two months after the operation the urine had cleared up; specific gravity was 1,015; and patient's physical condition was completely transformed. He now wears the tube without inconvenience, holds his urine for four hours comfortably, and says he feels ten years younger, and can work as well as ever.

In this case absolute relief of most distressing symptoms, including recurrent attacks of epididymitis, was attained. These symptoms had arisen during a well-conducted and regular use of the catheter. In this case a suprapubic prostatectomy would probably have proved fatal as the comparatively trivial operation which was performed was the cause of great shock.

A similar case was R., age sixty years, who had had prostatic symptoms for five years, and for three years had been obliged to use a catheter regularly. Soon after beginning its use he started up a urethritis, which

[1] Read at the Annual Meeting of the American Association of Genito-Urinary Surgeons at Harrogate, Tenn., June 14, 1893.

persisted up to time of operation. Then came a cystitis which gradually increased in severity, and was much aggravated by some anterior strictures which appeared (undoubtedly a result of the catheterization) and contracted down to 10 French. At the operation, the strictures were cut internally, a perineal section done, and catheter tied in. Moderate bilateral and middle lobed prostatic hypertrophy was found. Patient did well, and at once began to pick up. Continuous drainage was maintained for two months; and then, as in the other case, the urine was gradually allowed to collect in bladder until four-hours intervals were established. Symptoms at once ceased; urine cleared up; and now (eight months after operation) patient is perfectly comfortable, is wearing the perineal tube, and refuses to go back to catheterization or to have any radical operation done. He is about, in good health, and able to work comfortably.

The application of this idea of bladder drainage has been extended to include certain cases of suppurative pyelitis by some surgeons, notably Mr. Reginald Harrison, of London, who once said in a lecture:

"There are several advantages which might be urged in connection with what I would speak of as the tentative employment of perineal drainage in cases of kidney suppuration in the male, where from the symptoms and state of the urine, it was probable (*a*) that suppuration was going on in one or both kidneys, and (*b*) that the seat of suppuration evidently had a free access to the ureter: (1) Because perineal urethrotomy might be made to afford a means of continuous drainage, with or without a drainage-tube, at little or no risk; (2) because there is no fear of attacking the wrong kidney; (3) because it does not preclude the employment of further and more direct measures such as nephrotomy or nephrectomy, should these prove desirable."

He then goes on to report several cases, in one of which the drainage was kept up for six weeks or more, and made a good (and Mr. Harrison thinks a permanent) recovery. He concludes his remarks by saying that cases which are not likely to be remedied by such a proceeding are those of calculous pyelitis and extraneous abscesses opening into the kidney or ureter and discharging their contents into the bladder. In one case which he treated in this way the pus proved to come from a psoas abscess which had opened into the kidney. In this instance the patient received great comfort from the drainage, although, of course, no permanent good came of it. The urine remained acid in spite of the large amounts of pus which it contained, and the patient was spared much pain in voiding it.

The only case of the sort which comes within the writer's experience was one on the service of Dr. F. S. Watson, at the Boston City Hospital. The patient had perineal drainage for three months for what was thought to be a cystitis of six months' duration. The case proved to be one of calculous pyelitis, and is now rapidly convalescing from a successful nephro-lithotomy. Even in this case three months' perineal drainage gave great relief to the symptoms of pain, irritability, etc., which were not entirely reflex.

Leaving out of consideration cases of calculous pyelitis as manifestly unfit for such a method of treatment, there remain to us cases of renal suppuration of tubercular origin, and these probably form a large percentage of all cases of renal suppuration; those from extension upward of a purulent process; and those of suppurative pyelitis from other causes than those mentioned, chief among which, perhaps, are the cases due to crystalline elements in the urine.

The advisability of operating upon the tubercular cases is very doubtful, still the field is large enough to make a consideration of this method of treatment a very interesting one. In order to be at all in sympathy with it, one must agree with Mr. Harrison that such perineal drainage is more efficacious than catheter drainage through the urethra, and that the operation for such perineal drainage is simple, easily performed, and not attended with serious after-effects.

Mr. Harrison has also cured some very stubborn cases of chronic urethral discharge, which had baffled all previous attempts, by performing a perineal section, and thereby at once keeping the urethra very clean and very quiet.

Mr. Hall, in the London *Lancet* for February 19, 1870 (Vol. I, page 262), reports some cases in which he cured long-standing perineal fistulæ in this way.

It would seem that certain cases of spinal disease complicated with a chronic cystitis, as so many of them are, might also be made far more comfortable by a permanent drainage through the perineum.

In conclusion, the writer wishes to make no claim for this procedure as in any way a well-defined routine measure of treatment. It is undoubtedly a method of value in some cases; and he would suggest that among such cases may very properly be:

(1) Some cases of vesical and prostatic disease where the operation is done to palliate symptoms, when a radical operation is inadvisable or impossible.

(2) Some cases of suppurating pyelitis, not of calculous origin. Most tubercular cases are also probably outside the field of this treatment. Here the drainage would be tried as a palliative measure before resorting to severer ones, such as a nephrotomy.

(3) Some cases of obstinate urinary fistulæ.

(4) An occasional chronic urethritis.

(5) Cases of chronic cystitis, due to disease of the spinal cord.

The writer has not spoken of suprapubic drainage of the bladder in cases such as are instanced in this paper, because he has had no personal experience with that form of drainage in such cases.

SUBPHRENIC ABSCESS, WITH SPECIAL REFERENCE TO THOSE CASES WHICH SIMULATE PYO-PNEUMOTHORAX.[1]

BY A. LAWRENCE MASON, M.D.,
Associate Professor of Clinical Medicine in Harvard University; Visiting Physician, Boston City Hospital.

(Continued from No. 8, page 192.)

SUBPHRENIC ABSCESS FROM PERFORATION OF THE VERMIFORM APPENDIX.

That perforation of the vermiform appendix may give rise to abscess which extends to the arch of the diaphragm was observed by Duchek,[16] Bamberger,[17] Bernheim,[18] and other more recent writers, who have called attention to the interesting auscultatory features which air-containing abscesses in this region may pre-

[1] Read before the Association of American Physicians, Washington, D. C., May, 1893.
[16] Prager Vierteljahrschrift, 1853.
[17] Verhandl. der phys. med. Gesellschaft zu Würzburg, 1858, s. 123.
[18] Virchow-Hirsch Jahresbericht, 1874.

sent. Cossy [19] applies the term "false pneumothorax" (faux pneumothorax) to these misleading signs, and relates two cases of perforated appendix which presented this condition. In one case, on section, the anterior surface of the pericardium, when percussed, resounded like a drum, suggesting pneumo-pericardium, but this sound was found to be transmitted from the air-containing abscess beneath.

Similar cases of subphrenic abscesses of the right side with amphoric signs in the thorax are recorded by Jaffé [20] (Hamburg) and Herrlich,[21] who both operated unsuccessfully by thoracotomy. Large air-containing abscesses were found between the diaphragm and the right lobe of the liver and there was fistulous communication with the perforated appendix.

Starke [22] records a case of the same kind in which spontaneous cure followed the evacuation of the abscess through the bronchi.

Pätsch [23] effected a cure in the case of a boy, eighteen years old, who was seized four days before admission to the hospital with signs of peritonitis in the right iliac region. Two weeks later pain developed about the sixth and seventh ribs and there were signs of fluid encroaching upon the thoracic cavity without cough or expectoration. Exploration discovered foul pus, which soon after found exit through the bronchi. Incision above the seventh rib in the anterior axillary line resulted in early recovery.

Taylor [24] relates a case in which a large abscess was found between the liver and diaphragm caused by extension from a sloughing appendix.

Fitz [25] in his paper on "Perforating Inflammation of the Vermiform Appendix," read at the first meeting of this Association, says: "The extension of a secondary paratyphlitis may cause perforation of the diaphragm with a consecutive pleurisy or pericarditis." Such a case was then mentioned by Dr. W. W. Johnston, with the remark that such an untoward event would be rare at the present time, owing to early operative interference.

Leyden,[26] however, has lately recorded a case of "pyo-pneumothorax subphrenicus" in which an abscess containing more than two litres of pus had formed above the right lobe of the liver, having extended to this region through retro-cœcal suppuration, the result of perforative appendicitis. Intercostal drainage failed to cure, and after death it was found that the abscess had gone through the left wing of the diaphragm also. The hole in the appendix had closed.

PERISPLENIC ABSCESS.

Suppuration in the splenic region, except as the result of traumatism or pyæmia is rare. But Zuber,[27] in an article on perisplenic suppuration, reports cases of abscess in this region, the result of circumscribed peritonitis. They were bounded by the spleen, stomach, colon and diaphragm, and were said to have been caused by an "infectious splenitis" attributed to the poison of intermittent fever. Cases by Hilton Fagge, Grisolles, Villemin and others are quoted.

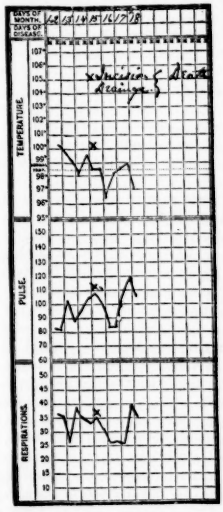
[27] C. Zuber: Des collection spurulentes péri-spléniques. Revue de Médecine, Paris, 1882, vol. ii, p. 928.

Wardell [28] refers also to the influence of malaria in causing latent splenic inflammation which may result in abscess below the diaphragm and secondary pleurisy or empyema. The same accidents may happen which result from abscesses in this region from other causes. The lung, stomach, or colon may be perforated.



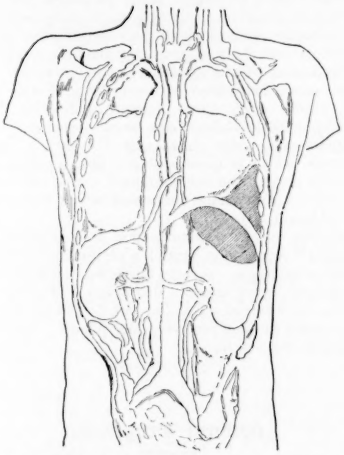
Jaffé [29] tapped a subphrenic abscess at the angle of the scapula and removed bloody, offensive pus. After death the spleen was found to have been ruptured by an injury.

Herrlich [30] reports a case in which the diaphragm was pushed up to the third rib by a large metastatic abscess in the splenic region. The signs of pleuritic effusion were present and pus was obtained by aspiration. The patient died before thoracotomy could be performed and the pleura was found to be free.

Councilman [31] reports the post-mortem examination of a case of perisplenic abscess with perforation into the splenic flexure of the colon, followed by thrombosis of the splenic vein and multiple abscesses of the liver, probably the result of an injury.

SUBPHRENIC ABSCESS FROM PERINEPHRITIC INFLAMMATION.

While lumbar tumor usually characterizes perinephritic abscesses, they may develop round the upper part of the kidney and are then contiguous to the diaphragm. By extension they may penetrate the lung or pleura. It was in this class of cases that the late Dr. Henry Ingersoll Bowditch, in a timely article on "Perinephritic Abscess," [32] urged the danger of chest complications and the importance of early and radical operation. He reported several cases which had come under his care. Roberts,[33] in a paper on "Perinephritic Abscess," also calls attention to the importance of chest symptoms in such cases. But they form a class by themselves, as a rule, with special symptoms, and I will not allude to them further except by the report of a case which illustrates the above-mentioned dangers.



CASE VI.

CASE VI (Mason). *Perinephritic abscess involving the diaphragm and pleura.* — A man, aged thirty-three years, entered the hospital with the history of pain in the right hypochondrium for a year, but he

[28] Contributions to Pathology and the Practice of Medicine, by John Richard Wardell, M.D., Edin., p. 72.

[33] Perinephritic Abscess: American Journal of the Medical Sciences, April, 1883.

had worked until the last week. He was emaciated and cachectic and had bulbous fingers. There were signs of fluid below the right scapula and tenderness over the lower intercostal spaces in the axillary line, with retraction of the same spaces in front, as if the lung were adherent. Liver and spleen enlarged and easily felt below the ribs. Urine, albuminous; large and small hyaline and granular casts. Ten ounces of foul-smelling pus were withdrawn by aspiration at the eighth space, posterior axillary line. The proximity to the diaphragm, the adherent lung, and the pain, gave rise to the opinion that there was a latent subphrenic abscess with secondary empyema. The enlarged liver and spleen and the urinary changes suggested amyloid degeneration. An incision was made in the ninth space behind, and the cavity was irrigated, but the patient soon died from septicæmic exhaustion. Cough, expectoration and râles, chills, sweating and vomiting had been noticeably absent. The temperature was subnormal.

Case VI. — Perinephritic abscess (tubercular); secondary empyema; back view.

Autopsy: At autopsy the right pleural surfaces were adherent throughout, except at the lowest posterior part, where there was an abscess cavity. Below the diaphragm and surrounding the upper part of the kidney was another abscess, the diaphragm being necrotic. Amyloid spleen and kidneys. Tubercular deposits in lungs and liver.

GALL-STONES.

Gall-stones show little tendency to excite suppurative processes in their vicinity. Fenwick cites five cases in which they had caused abscesses which burst into the duodenum, but such instances are rare and their course is more acute than that of the abscesses caused by perforating ulcers.

SUBPHRENIC ABSCESS FROM CANCER.

Cancer is an infrequent source of sub-diaphragmatic abscess, but such cases are referred to by Andral,[34] Habershon,[35] and Fenwick.[36] Neusser[37] relates the following: A woman, aged thirty-six, had a large cavity filled with pus and air between the liver and diaphragm on the right side, communicating with a deeply ulcerated cancer of the pylorus which had been diagnosticated during life. There was perforation of the diaphragm and gangrene of the lung.

LITERATURE.

When we turn to the literature of this subject we find that it is fragmentary, but it is no less interesting to watch the progress of auscultatory science and physical observation than the advance of surgical art in dealing with these difficult cases.

In 1829, Wright[38] records two cases of "pneumohepatic" abscess as occurring at the Baltimore Almshouse. In one there was recovery after the spontaneous discharge of air and pus between the eleventh and twelfth ribs near the spine. Pain, fulness and threatened suppuration at the epigastrium were noted, and were attributed to abscess of the left side of the liver, but the diagnosis was uncertain. In the other case there was a double abscess, containing air, in the lung and the liver, with communication through the diaphragm.

Graves and Stokes[39] record a similar case in which an abscess resting on the convex surface of the liver had involved the lower lobe of the right lung. Incision between the eighth and ninth ribs gave exit to a pint of sanious pus. Through the opening air escaped with force on coughing. The autopsy showed that the diaphragm had been perforated, but it was not clear whether the pulmonary abscess or the one below the diaphragm was primary.

The recognition of the relation between perforating gastric ulcer and the signs resembling pneumothorax has been attributed to Barlow and Wilks, who first reported such a case in 1845, under the title, "Perforation of the Stomach, with Obscure Thoracic Symptoms."[40]

Case. — A female, aged thirty-nine years, was admitted to Guy's Hospital, October 26, 1844. History of gastric ulcer for eighteen months. Two days before admission she had an attack of sudden dyspnœa and intense pain. The epigastrium was prominent, very resonant, and tender. There were signs of pleurisy at the left base, with also amphoric respiration, metallic tinkling, "Punch's voice," and succussion splash. Over the præcordia was a rubbing sound, synchronous with the heart-beats and heard when the patient held her breath. This was thought to denote pericarditis. Death took place twenty days after entrance. "The stethoscopic signs, particularly the amphoric respiration, coupled with the severe symptoms, satisfactorily proved to many that the case was one of pneumothorax. Dr. Barlow was opposed to this opinion and persisted in referring the amphoric and metallic sounds to the stomach, and mentioned a case in which a perforation of the stomach had communicated with a large peritoneal abscess." This proved to be the case, and, although there was a pleural effusion, no communication existed between the chest and the abscess below the diaphragm. There was no pericarditis.

Case. — Williams,[41] in 1845, recorded the case of a man, forty years old, who, after dysentery, had an abscess between the right lobe of the liver and the diaphragm, which

[41] Loc. cit., December, 1845.

was later incised at the right hypochondrium. After death it was found that the metallic tinkling which had been observed had been produced by a communication between the abscess and the transverse colon.

Wintrich [42] says that when he was clinical assistant at Würzburg a mistaken diagnosis was made in the case of a woman in whom there was a large abscess cavity filled with gas, débris of food, and pus, connected with a perforating ulcer of the stomach. Pneumothorax was diagnosticated from the presence of metallic tinkling and percussion note, amphoric breathing, dyspnœa, cough and expectoration.

Habershon,[43] Bouchaud,[44] Hilton Fagge,[45] Taylor,[46] and others have recorded a variety of cases of this description. Fagge's sixteen cases of "Abscess of the Upper Abdomen" from various causes are especially interesting.

But the subject attracted little general attention until 1880, when Leyden [47] published his well-known article entitled "Pyo-pneumothorax Subphrenicus," a designation which is evidently open to objection, but which explains itself clinically. From Leyden's clinic, through Herrlich,[48] Pfuhl,[49] Scheurlen,[50] and other writers comes a large part of our information on this subject. Leyden's original article related to four cases of air-containing abscess below the diaphragm. After having, in the first case, diagnosticated pyo-pneumothorax in a twenty-three-year-old female, he found, to his surprise, post-mortem, that the signs were produced by an abscess above the liver, which communicated with a perforating ulcer of the duodenum. After this experience he correctly diagnosticated three similar cases, one duodenal and two gastric perforations. All proved fatal in spite of surgical treatment, carried out in one case by Langenbeck. In another case six exploratory aspirations failed to find the abscess, which, after death, was seen to originate in the vicinity of a closed gastric ulcer, which the author regarded as its undoubted cause.

Leyden's diagnostic points were in part:

(1) Previous abdominal symptoms, and absence of signs of thoracic disease in the early part of the illness.

(2) Little displacement of the heart or bulging of interspaces.

(3) Normal respiration under the clavicle, with abrupt transition lower down to the metallic and amphoric sounds which occur in pneumothorax.

But it is to be observed that the heart is often displaced by the coincident pleural effusion, as in Case V, and abrupt change in percussion tone is not always found. Moreover, the lung often adheres to the diaphragm and parietes, with partial loss of contractility, so that, although there may be a diminution in the breath sounds and vocal fremitus, they are not entirely abolished as in general pneumothorax. Cough and bronchial discharge aid us in diagnosticating a circumscribed pyo-pneumothorax.

From Leyden's clinic and other sources, chiefly German, Scheurlen [51] collected 34 cases, including two of his own, in one of which a cure resulted after resection of the ninth left rib in the anterior axillary line. The cause was perforating gastric ulcer. Half the cases were diagnosticated during life and 15 were operated on. Six recovered, but in one only was the cause a perforating ulcer. The earliest cure was recorded by Pätsch in the case of subphrenic abscess from appendicitis quoted above. The seat of the abscess was on the right side in 19 cases; on the left in 15. The causes were gastric ulcer, 11; duodenal ulcer, 4; perforation of vermiform appendix, 6; trauma, 3; hepatic or peri-hepatic abscess, 2; peri-splenic inflammation, 2; cancer of pylorus, 1; suppurating echinococcus cyst, 1; a swallowed hairpin, 1; and in 3 the cause was not determined. Pleural effusion existed in 16 cases; in 6 there was perforation of the lung through the diaphragm; in 2 pyo-pneumothorax, and in several others the deceptive signs which simulate that condition.

Scheurlen regards the absence of the usual causes of empyema, namely, tuberculosis, pneumonia, and the puerperal state (to which might be added the acute fevers), as important in aiding a diagnosis by exclusion. As valuable physical signs, he mentions the friction sound of dry pleurisy near the diaphragm, and the disappearance of the semilunar space in the left side, which occurs in pleurisy with very large effusion only. But without exploratory puncture, Scheurlen thinks that subphrenic abscess can be suspected only, not diagnosticated. He states that the pus is always ichorous, which is questionable. The withdrawal of pleuritic serum from one interspace, and of pus from a lower level is a valuable indication, which was also observed in our Case III.

A more recent communication from Leyden and Renvers [52] reports the cure of a perigastric abscess by puncture drainage. A large trocar was passed through the seventh space and the diaphragm. Through the canula, by means of a Nélaton catheter, the cavity was washed out without involving the pleura. Recovery ensued in one month.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASE.

BY GEORGE G. SEARS, M.D.

PULSUS BIJEMINUS AND DEATH FROM DIGITALIS.[1]

HUCHARD found that digitalis in many persons leads to a perversion of the cardiac rhythm, which has received the name of pulsus bijeminus. Two revolutions of the heart follow each other rapidly: the first is usually the stronger and is easily felt in the pulse, while the second may be so weak as to be scarcely, if at all, indicated there. This peculiarity is also found in many arterial cardiac lesions from their tendency to produce cardiac dilatation; but it is often overlooked, either because it is transitory or because it is mistaken for an irregularity. Each pair of beats is separated by a more or less well-marked interval, which prolongs the duration of the systole and thus increases the amount of blood which flows into the ventricles and distends their weakened walls. Then

[1] Centrblt. f. d. ges. Ther., 1892, p. 575.

[52] Berliner klin. Wochenschrift, November 14, 1892.

two systoles follow each other quickly in order to thoroughly empty the over-full ventricle. As digitalis increases the period of diastole, it favors the production of this abnormal rhythm, and in these cases must therefore be withheld, as it may lead to rapid, or even sudden, death, with symptoms of cardiac dilatation and cyanosis.

THE GRAPHIC METHOD APPLIED TO THE DIAGNOSIS OF OBSCURE ANEURISMS.[2]

Apropos of Dr. Richardson's proposition to employ intra-thoracic auscultation in the diagnosis of obscure conditions within the chest, Fenwick and Overend say that in 1890 they made a series of experiments in this direction. Beside practising auscultation by means of the œsophageal tube, they attached a Marey's tambour in the hope of obtaining graphic records of the movements communicated to various parts of the œsophagus, with especial reference to the diagnosis of obscure aneurisms. This was tried in several cases with considerable success; but in their final case, though every precaution had been taken, and the signs of aneurism were at the time obscure, the straining and retching caused by the tube brought on an immediate hæmorrhage, which frightened the patient and occasioned them the gravest misgivings. Although it is rational in device, easy of performance and undoubtedly serviceable in diagnosis, the extra risk of life, in their opinion, cannot compensate for its probable disadvantages, no matter how fine or flexible the tube may be. They therefore discourage its use.

MEDIASTINAL PLEURISY.[3]

Velimirowitsch bases his thesis on the study of five well-marked cases, all of which occurred in children, two coming under his own observation. He realizes the difficulty of drawing an adequate picture of the disease from the meagre material at his command, but makes the attempt owing to the lack of previous endeavors in this direction. A frequent cause of the affection is tuberculosis. It is more often situated on the left than on the right side of the thorax and is most common in children. The symptoms are often so similar to pericarditis that during life they are frequently mistaken, one for the other. An important point in diagnosis is the character of the onset, which is usually accompanied by severe pain between the nipple and sternum and a sense of great oppression. In effusions in the left side there may be bulging of the precordial region and obliteration of the intercostal depressions, with a tympanitic percussion note below the clavicle, dulness over the sternum and feeble vesicular breathing in the anterior portions of the lung. Displacement of the heart may also be looked for, the sounds being modified and feeble and distantly heard on the right side. In effusions on the right side, the symptoms are the same, but cardiac displacement does not occur. In some cases the liver is pushed downward. The prognosis is not good, but depends on the underlying disease. Treatment is practically confined to puncture.

MULTILOCULAR PLEURISY.[4]

Rudolph says that adhesions between the visceral and costal layers of the pleura are so commonly found resulting from many different causes, that it is probable that multilocular pleurisies are not such very rare occurrences. The cavities are usually two in number, but may be more; at times they communicate with each other, at others they are entirely separate. In the latter case the fluid in the different cavities may vary greatly in character, one, for example, containing serum, another pus. Though Jaccoud was able to recognize two forms of this condition, in one of which all the classical symptoms of effusion are present, except for a more or less crescentic-shaped zone extending from spine to sternum, where vocal fremitus and the respiratory murmur are still preserved, and another in which, with flatness on percussion and displacement of neighboring organs, vocal fremitus, marked bronchophony and bronchial breathing are all present. Rudolph, in four typical cases, had no suspicion of the real condition in one case till the autopsy, and in the other three, till after the first pocket had been tapped. If, after thoracentesis, when done in the back, the signs of pleural effusion still remain anteriorly, in the right side above the limit of hepatic dulness, or on the left, over the semilunar space, there can be little doubt of a second effusion. Another point in the diagnosis of this condition is the withdrawal of less fluid than the amount of the dulness, etc., would lead one to expect, while the persistence of fever after the evacuation of an empyema is a very suspicious symptom, provided other causes can be ruled out.

The prognosis depends on the character of the primary disease: cases in which the contents of the cavities are of different characters are almost always the result of serious lung diseases, tuberculosis, bronchiectasis or carcinoma.

ACCIDENTS OF NERVOUS ORIGIN CONSECUTIVE TO THORACENTESIS AND EMPYEMA.[5]

Jeanselme has collected forty-five cases of this sort, in which the nervous manifestations varied greatly; syncope, convulsions, hysterical and epileptic attacks, monoplegia and hemiplegia, delirium, strabismus, disturbance of vision as well as vaso-motor and trophic disturbances, being among the number. As premonitory symptoms he has found inequality of the pupils, the dilatation being present on the side corresponding to the empyema, hyperæsthesia of the pleural fistula and pleural hæmorrhage, but almost always the onset is sudden and stormy. They do not occur spontaneously in the course of the disease, but invariably after operative interference, rarely after a simple operation, most commonly after washing out a pyothorax, but the nature of the irrigating fluid is unimportant. It rarely occurs in cases of serous effusion, but three cases out of forty-three, in which the character of the fluid is mentioned, being of this kind. The prognosis is not good, as over half the cases proved fatal.

Individual cases may be traced to an embolic, cardiac, toxic, uræmic, epileptic, traumatic or hysterical origin, but underlying them all is a state of poor nutrition, cachexia or similar conditions in which nervous crises develop at the first opportunity, the central region which is responsible for these manifestations being probably the medulla. The treatment should be supporting and stimulating. As a prophylactic measure too much fluid (1,000 to 1,200 g.) should not be withdrawn and care should be taken in washing out the pleura and in the use of the irrigator.

ON THE TREATMENT OF BRONCHIECTASIS.[6]

Stewart says that while the generally accepted theory is, that bronchial dilatations are produced by the contraction of fibrous tissue in the lungs, that process does not explain many, and indeed, the most typical, examples of the disease. For bronchiectasis is often present when there is no cirrhosis and in not a few cases the fibroid change follows upon it as a secondary consequence. Further observations have confirmed the views which he expressed twenty-six years ago that an atrophic process in the walls of the bronchial tubes affords the real explanation, and that, given such an atrophy, the pressure of the air in the respiratory tract leads to dilatation of the tubes, while the consequent accumulation and decomposition of the mucus produce further changes characteristic of the disease. He has therefore endeavored to adopt treatment which would meet these conditions. Very little, however, can be done to prevent the occurrence of atrophy, nor, except by keeping down cough so far as that was warrantable, to interfere with the pressure conditions which tend to dilate the weakened walls. The constant aim has been, therefore, to prevent the decomposition of the sputum and its consequences. Turpentine, creasote, carbolic acid, salol and other antiseptics by the stomach, as well as sprays and vapors of various kinds have all been sedulously tried, with on the whole a very limited and temporary advantage. In one case during the past winter he had used an intratracheal injection of menthol (10 parts), guiacol (2 parts), and olive oil (88 parts), a drachm being injected into the trachea twice daily. The injections were given regularly for about a month and then gradually less frequently, with the result that in a week the fetor of the breath and sputum had entirely gone. The temperature speedily fell to normal, the general symptoms disappeared, the weight increased, the appetite returned and the digestive process became established, while the pulmonary signs had been favorably modified. Had this treatment failed Stewart proposed to try operative interference and gives details of a case under his care several years ago in which such treatment was adopted with good result.

SECOND DAY. — MORNING SESSION.

DISCUSSION ON MYXŒDEMA.

A PAPER by DR. F. P. KINNICUTT, of New York, was read by DR. W. G. THOMPSON.

This was followed by a paper by DR. JAMES J. PUTNAM, of Boston, who reported two cases of myxœdema successfully treated by thyroid preparations of different kinds.

The first case was that of a lady in middle life who had had the disease for upwards of twelve years in a pronounced and typical form. The treatment by injection was begun in July, and the improvement began to show itself in two weeks. She is now practically well, though still anæmic and delicate; and from having previously been bald, she has a dense growth of hair. The history of the case furnished some facts with regard to the morbid symptoms occurring during the thyroid treatment, and these were considered also with reference to other cases. Their cause is not so much the thyroid extract itself as it is the rapidly changing condition of the heart and blood-vessels, and perhaps the rapid absorption of substances from the tissues.

The second case was that of a lady in whom myxœdema appeared about the time of the menopause; and it is especially interesting on account of a family tendency to the disease, the rapidity of the improvement, and the fact that, for several years before, the thyroid had been enlarged (as it is still) and tachycardia had been present.

A third case was important on account of a history of severe headaches associated with atrophy of both optic nerves. There was some doubt as to the diagnosis of this case, and the discussion of it brought up the question of the relation of myxœdema to acromegalia, two cases of which are now under the writer's observation. Both of them have been treated by thyroids, and appear to have improved.

The relation of myxœdema to Graves's disease was also discussed; and the view was maintained that we have not at present sufficient grounds for asserting any very close relationship between these affections. It is not probable that Graves's disease is due to enlargement of the thyroids in the same sense that myxœdema is due to an atrophy of that organ. Certain forms of obesity, perhaps, stand nearer to myxœdema, and the latter disease in the modified form is perhaps more common among elderly people than has been supposed.

The results of partial thyroidectomy, which appears to have been so successful in relieving the symptoms of Graves's disease, form an argument of value in favor of the thyroidal origin of that affection; but the question can by no means be decided positively on that side. The evidence that Graves's disease is essentially a cachexia due to disordered tissue nutrition, in the same sense as with myxœdema, is not strong, and the theory that the symptoms are due to excessive or vitiated thyroid secretion, though important, still lacks proof. The occasionally rapid onset of Graves's disease under excitement or nervous shock is not easily explained in that way, though not positive disproof of the theory. The truth probably is, that Graves's disease is closely related to the cardiac-regulatory and vaso-motor functions of the thyroid, and very little to its trophic functions. It is difficult to define the condition of the thyroid necessary to produce myxœdema, etc. Sometimes its functions seem to be only temporarily inhibited. It is probably not true, however, that a small part of the gland is functionally equivalent to the whole.

The recent observations respecting the pathological anatomy of the myxœdematous condition were cited, and the conflicting evidence regarding the supposed compensatory enlargement of the hypophysis cerebri after thyroidectomy, and regarding the function of the hypophysis. There is, perhaps, an analogy between the cachexia thyreopriva and eunuchism after castration.

[6] British Medical Journal, June 3, 1893.

Another paper was read by Dr. M. Allen Starr, of New York.

Dr. Starr's paper consisted of a report of three cases successfully treated with the thyroid extract and the discussion of the mental condition present in all of his cases.

Case I. Female, forty-six years of age, from Newcastle-on-Tyne, England. Developed myxœdema in April, 1882. Various forms of treatment failed to give her any relief. First seen in Dr. Starr's clinic, College of Physicians and Surgeons, New York, February, 1892. Was put upon glycerine extract of thyroid gland in March, 1893. Was given six drops of the glycerine extract, three times a day, increasing the dose one drop daily. Improvement began within ten days, and has been progressive and continuous. This improvement has affected both body and mind, and in every respect the change for the better is marvellous. The œdema has practically vanished. Her mental condition has improved to even greater extent than her bodily state. She is able to walk several miles a day when formerly it exhausted her to walk 800 feet. She is free from pain and sleeps well. Her temperature has steadily risen under treatment from 97°, and is now constantly normal. The dose of extract was steadily increased until she was taking ten drops three times a day, at which point it caused a feeling of exhaustion. The pulse was found to be over 100 and the temperature 99.5°. The dose was reduced to eight drops, and subsequently maintained between eight and nine drops three times a day for the past month. This is the equivalent of a half a gland daily.

Case II. Female, twenty-two, single. The onset of the disease was so gradual that it is impossible to say when the present symptoms first developed; but it is certain that in 1889 her appearance was noticed to be peculiar, the face being swollen and waxy in its pallor. On January 6, 1893, put upon thyroid extract, five drops three times a day, increased gradually up to nine drops three times a day. The improvement began three weeks after the beginning of the treatment. On May 1st, her condition had markedly changed. The œdema had disappeared from the face, the body and the extremities, the tongue and lips alone being then affected. The skin was soft, and no longer scaly and dry; had some color; well-nourished, good digestion; and mental condition apparently normal. Walks three miles daily, and is fairly well. Is now taking thirty drops daily of the thyroid extract, which is equivalent to half a gland.

Case III. Female, aged forty-six, married. Suffering from myxœdema since 1880. Put upon thyroid extract four months ago, ten drops three times a day. The reaction was so intense as to give rise to much alarm. After an intermission of a week, treatment was begun in five-drop doses twice daily, and then gradually increased to ten drops three times a day. This dose she can take without manifest discomfort. After four months' treatment her appearance is wholly different from that of the past six years. She no longer has the appearance of undue obesity. The skin, which was formerly dry, rough and scaly, is now soft and smooth; and she says that she is beginning to perspire naturally, a thing she has not done for ten years. There is a perceptible new growth of hair on the head and in the arm-pits. The supra-clavicular swellings, which were very noticeable, have gone away entirely. Her speech is different in character; her facial expression has markedly changed for the better; her appetite and digestion are good. Urine increased in amount. Her mental depression has passed away.

Dr. Starr, after a consideration of the mental symptoms observed in his patients, concludes that these mental symptoms must be due to certain physical changes in the brain, probably similar in nature to those visible in the body, especially when the relief of the mental symptoms by the treatment with the thyroid extract is taken into account.

Dr. W. G. Thompson, of New York, then gave the following history of a case of myxœdema:

The patient is a female, forty-four years of age. Symptoms of œdema commenced twelve years ago. Admitted to Presbyterian Hospital, April 5, 1893. Had the characteristic symptoms of the disease. After four days under observation without treatment, she was given daily doses of five minims of glycerine extract of the sheep's thyroid, prepared by Dr. Geo. W. Crary. No reaction was at first observed, and the dose was increased by one minim with each dose until a week ago the patient was taking twenty minims three times a day. Patient now under treatment fifty days. Temperature has fluctuated three degrees, ranging between 97° and 100°, most of the time being subnormal. At first the daily fluctuations amounted to 2.5° or 3°, but of late they have been only 1°. The hair has continued to fall out, but the extensive lamellar desquamation has ceased; and the skin over the hands and arms has become more elastic, softer and much less dry. Ten days after the treatment was begun the swelling of the face, especially about the eyes, had decidedly diminished, and the lips and tongue became slightly thinner. The patient's mental condition improved considerably. The feeble circulation has not improved, but the patient sits up daily and moves about the wards. There has been a slight increase in the daily production of urea. The extract, as prepared by Dr. Crary, represents twenty-four grains of gland tissue to the drachm of glycerine. Strict surgical cleanliness is observed in all the steps of the process. Boric acid solution is the only antiseptic used, heat sterilization being employed. The glycerine is Schering's twice distilled, sterilized before being used. The glands are cut up separately, those diseased thrown out. After standing four days the extract is ready. After two months it seems to lose something essential.

Dr. F. C. Shattuck wished to mention, rather than report, three cases of myxœdema, two in private, one in consulting practice.

Upwards of a year ago a single lady of twenty-nine was brought to him with symptoms dating back a number of years, but more aggravated within a few months. Her appearance had so changed that people did not recognize her. Her mental condition was one of rather undue elation. Early in May, 1892, he injected weekly a glycerine extract of a sheep's thyroid in three doses. The injections were kept up for about three months. The skin improved very much; but from undue elation she passed into a condition of suicidal melancholia, which has continued more or less up to the present time. About two months ago she began to take Parke, Davis & Co's dessicated thyroid extract by the mouth, fifteen grains twice a day, and continued it for five weeks. It was then stopped on account of pains in the legs, and afterwards resumed. She is essentially no better, although she has been fairly subjected to the treatment.

The second case is that of a gentleman of sixty-nine, seen first two and one-half months ago, in an early stage of myxœdema. He was put upon dessicated thyroid, fifteen grains twice a day in capsules. Before many days he began to complain of pains in his legs, and then in his chest near the cardiac region. The dose was diminished to seven and one-half grains twice daily. The myxœdematous symptoms rapidly abated; but the treatment soon had to be stopped on account of the very severe nocturnal paroxysms of pain like that of angina, demanding morphia hypodermically, several nights as much as two grains in half-grain doses. This was accompanied by great tenderness just outside the left nipple, and inability to lie on the left side. As the pain came the pulse would rise to 120, the normal rate being about 70. After three weeks' intermission the extract was resumed in the dose of one grain every second day, and he is now getting one grain daily. His whole appearance has undergone a marked change, and he feels better than for two years. Both he and his wife now date his symptoms back farther than they did at first.

The third case, which was seen in consultation, is of many years' standing, although she was seen but very recently. Very marked improvement has taken place; and her friends note a great change in her appearance, which was highly suggestive of Bright's disease. She has had much palpitation since she took the extract, seven grains three times a week.

The especial points to which Dr. Shattuck called attention were the failure of the treatment thus far in a case which seems undoubtedly one of myxœdema and the toxic symptoms noted more or less in all three, namely, pain in the legs, palpitation and severe angina. We are dealing with a powerful agent, and should be very careful until we are more familiar with its doses than we are at present. Among the many points which experience will enlighten us upon is the relation of the dosage to the duration or intensity of the disease. The descriptions of myxœdema, as laid down in the books, apply to old and very marked cases. As we learn to recognize the early stages of the affection, we shall find that cases are pretty common.

DR. WM. H. WELCH spoke of the results that Dr. Halsted had obtained from extirpation of the thyroid gland in the dog. A singular alteration in the structure of the gland, which had been referred to in the papers on myxœdema as an "hypertrophy" of the gland, had been found. The change is so complete an alteration of the structure of the gland that it is doubtful if any one would, in an advanced degree of the change, recognize sections of the organ under the microscope as thyroid gland at all. The appearance of follicles has disappeared, and the lumen of the follicle is filled up with papillary growths from the walls of the follicle. There is complete disappearance of the colloid substance from the lumen of the gland, and the low cubical epithelium has become high cylindrical epithelium, and more granular than normal. This change occurs as the result of interference of various kinds with the gland, such as a very severe operative interference in the neighborhood of the gland or a simple handling of the nerves or a ligating of the nerves in the neighborhood or disturbing the tissues around the gland. The same change occurred in the glands of dogs which had been operated upon at a distance from the neck, as for intestinal suture and experimental peritonitis. In a series of something over one hundred dogs examined at the pound in Baltimore, a small percentage had this enlargement and alteration in the structure of the gland. All this shows that the thyroid gland has important functions, but still obscure.

Dr. Halsted has discovered the possibility of removing a great many times the weight of the normal thyroid. He takes away one thyroid gland and part of the other, but not enough to kill the animal. The part which remains behind hypertrophies and after a certain time is bisected. The operation is repeated again and again and a great many times the normal weight is taken away and absolutely no symptoms appear. During all this time the remaining portion of the thyroid is altered in the manner before described. Anything that bears upon these changes in the thyroid may prove hereafter of importance in the understanding of the function of the gland.

DR. J. J. PUTNAM, referring to the remarks of Dr. Welch, said that he had recently had a patient with exophthalmic goitre, operated upon by Dr. Warren, who removed about two-thirds of the gland. The part removed was examined by Dr. Councilman, and was similar in structure to the hypertrophied glands described by Dr. Welch. If only a very small portion of such a diseased gland is left, it seems to be sufficient to prevent the peculiar cachexia from coming on.

Parke, Davis & Co., and others who have been concerned in securing the thyroids from sheep, have found large numbers of them diseased. About one-third of those examined at the Brighton Abattoir were found diseased, and were rejected.

The changes in myxœdema are often in such form as to strongly suggest nephritis. In two instances known to Dr. Putnam the diagnosis of nephritis was made. It is a subject for investigation, whether some of the obese elderly people whom we see with more or less of this œdematous condition are not subjects of myxœdema, and could be improved by thyroid treatment.

DR. M. ALLEN STARR, of New York, called attention to the necessity of varying the doses of the drug somewhat in accordance with the reaction of the patient. Different individuals are apparently differently susceptible to the thyroid extract. In one of his cases, owing to a misunderstanding between physician and nurse, the dose was run up to twenty-two drops of the glycerine extract three times a day, which is equivalent to two and one-fourth glands per day. This was not followed by any apparent ill effect. In Dr. Thompson's case no effect at all was seen until the dose was run up to eighteen drops of the extract three times a day. It is better to gradually increase the dose until pretty large doses are given. Recently, in the discussion in Edinburgh, on myxœdema, from out of a large number of cases reported (nearly seventy), there were but two cases of failure to relieve the patient by the use of thyroid extract.

Recent Literature.

The Anatomy and Surgical Treatment of Hernia. By HENRY O. MARCY, A.M., M.D., LL.D., etc. Published by D. Appleton and Company, New York. 421 pages, illustrated by 8 colored plates from Bougery, 66 full-page illustrations and 37 cuts.

This is an elaborate volume. Also one which on account of the skill and art of the publisher will al-

ways attract attention. It seems at first sight from its size, its attractive binding, its elegantly colored plates, its large pages filled with quotations, extracts, statistical tables and diagrams a monument of erudition. It has evidently been the aim of the author to contribute a work which shall be a "classic" in surgical literature. Its title describes accurately its contents. It tells of the anatomy and surgical treatment of hernia.

A close examination of the volume, however, results in a certain amount of disappointment. The expectation of the reader that he has found a complete treatise on hernia is not realized. There is much information relating to its descriptive and pathological anatomy. There is an exhaustive collection of bibliographical quotations relating to the history and development of its operative treatment, to the methods for its permanent relief and to statistical results, an elaborate chapter on the history and use of animal tendons in surgery, and finally, a detailed description of the operative method devised and practised by the writer of the work.

One finds a splendidly published volume containing a large amount of useful information; but also, unfortunately, such a mass of heterogeneous material and data compiled from discussions of surgical societies or personal correspondence that the reader is exhausted in his search for results or conclusions. There is a lack of appreciation of the relative importance of subjects. There is at times an account of abridged quotations and incorrect impression given of the true method or opinion of the original writer. There has been collected a huge mass of material both historical and recent. The task must have been a very laborious one. The compilation, the arrangement, the conclusions of this extended study and investigation, however, except so far as the writer's individual method and clinical experience is concerned, shows an inability to handle this mountain of data; or a lack of care in its preparation. These elements render the volume unsatisfactory for practical reference and arouse distrust as to the correctness of the quotations and statistics. The method of describing plates is tedious and requires an unnecessary expenditure o time.

The book is valuable in that it will furnish to a careful reader much valuable information relating to the descriptive and pathological anatomy of hernia. It will give him an interesting account of the ancient history of hernia. It will furnish a full bibliography of the literature describing its operative treatment. It gives an elaborate detailed description of the especial operation for the radical treatment of hernia devised and advocated by Dr. Marcy. The evidence now at hand as to the value of this operation comes chiefly from the publications of its originator. According to his reports it has given satisfactory results. In seventy-eight cases four recurrences. In two of the latter a second operation was ultimately successful.

The book is one which will never become popular as a volume for "practical" reference. It contains, however, much that is of interest, but in a form that requires some familiarity with its text to be available.

Lessons in Physical Diagnosis. By ALFRED LOOMIS, M.D., LL.D. Tenth Edition, revised and enlarged. New York: William Wood & Co. 1893.

The ten editions of this excellent book well attest its continued popularity. Some parts of the present edition have been rewritten, and a new lesson on "Clinical Microscopy" has been added.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, AUGUST 31, 1893.

283 WASHINGTON STREET, BOSTON, MASS.

THE MUTUAL INTEREST OF THE MEDICAL PROFESSION AND INSURANCE COMPANIES IN THE PROLONGATION OF LIFE.

THE above is the title of a paper read before the American Medical Association in June of the present year by Prof. Chas. Denison, of Denver, Col. Since that date it has been somewhat widely circulated as a printed leaflet.

In brief the essay presents a dual proposition:

First, that the medical profession shall adopt a systematic and uniform method of recording the symptoms, physical signs and progress of diseases of the chest, both for the study of such disease and the co-laboration of physicians in selecting a proper climate for the treatment. A special form for such record called a "Diagnosis Chart" and advice to supplement the same by spirometrical and manometrical observations, were presented with the essay, and two ingenious instruments for general and particularly for life-insurance examiners' use, devised by Dr. Denison, were described.

Second, that life-insurance companies being interested in the prolongation of life, as well as in the early and correct diagnosis of diseases of the chest, shall employ physicians especially qualified, to whom insured persons having such disease, shall be referred at the companies' expense, for examination and advice.

Further, that the companies upon report from these referees, shall look after the personal welfare of those requiring aid, and shall, if desired, loan them money to assist them in going to favorable climates.

The value of the first part of the dual proposition is evident, and especially so, since if generally adopted, physicians who examine for life insurance would be the better qualified for their duties.

Aside from the use of the spirometer and manometer, which, while impressive as office ornaments, are apt after years of service to stand disused and forgotten, what is the prospect of the adoption of the suggestion in connection with life insurance?

We must accept human nature as the past has shown it. The present only repeats the past; and the probability of bringing about the general use of charts and instruments of precision, is hardly less remote than in the years immediately following the discoveries of Lænnec. The great bulk of mankind do not care to be accurate, and the average medical practitioner is no exception.

That physicians who examine for life insurance — about eighty per cent. of whom live in thinly-settled districts, and who although the best attainable, are far from being highly educated — can be relied upon for a refined diagnosis in a case of a man not seriously ill, is at least problematical. Many of these men started out in life impressed with the importance of auscultation and percussion, but have gradually come to give less and less time to all but those acutely ill.

The experience of a medical director for more than twenty years shows that busy and skilful practitioners will not take the time to fill out a complicated chart, either for their patients or a company.

Those examiners interested equally by desire for the fee and a desire to please the agent (and these are unfortunately many), cannot be made to do it; and the country practitioner too often cannot do it correctly, if he would.

This statement is not meant as a reflection upon these physicians. They are able to detect disease. They are qualified to pronounce judgment upon a man's physical soundness; and their experience, backed by honesty and integrity of purpose, is a safeguard to the companies they represent. Yet they do not feel called upon to state in accurate terms the particular phase of disease they find; and if they were, would hesitate to record it for the possible criticism of jealous rivals.

The basis of life insurance is the known experience of mortality in the community at large; and the fair and honest opinion of a medical man conversant with the personal history of the men examined, re-enforced by the judgment of the medical directors of a company, would, of itself, be a selection which would keep that company's mortality within the tables, whether the examiner were an accurate diagnostician or not. Unfortunately, however, such fair and honest opinion is not always available. The personal interest of an applicant and the pecuniary interest of the solicitor, introduce such elements of danger that the most skilled physicians (being also the most independent) are the most desired as examiners.

The higher education of all physicians in the diagnosis of incipient disease is a matter of grave importance to life companies; but elaboration of detail and minuteness of record are fortunately not necessary concomitants. *Experientia docet;* and instead of elaboration, the larger life companies have gradually reduced the size of their applications, eliminated much that was once deemed essential, and simplified the questions to be answered.

The one object of inquiry, the pivotal point around which all examination centres, is not what special form of disease the applicant has, but has he any at all? In other words, Is he sound? If not, a wise company will take no chances. All doubts on the subject are, however, weighed and investigated by the medical directors, the integrity of the examiner being as important a factor as his ability, in the final decision.

That we may not be misunderstood we would sum up our observations on the first part of the proposition as follows:

(1) Life companies appreciate the importance of employing the most skilful physicians.

(2) The use of charts and instruments of precision is eminently desirable; and while experience in this direction hardly warrants the hope of their general adoption, the limited number who may adopt them will be considered by companies as preferable examiners.

(3) Nevertheless companies will still be obliged to employ many who are only relatively the best.

(4) The character of the business makes it necessary, and the broad, general principles of life insurance make it safe, to accept examinations by many whose experience and honesty of purpose are more pronounced than their skill in diagnosis of chest diseases.

The second part of the proposition, namely, that life companies can properly take measures to prolong the life of their insured who have developed disease of the lungs, presented as new, will undoubtedly have the charm of novelty to many, and is worthy of consideration.

We must not mistake the true purpose of life insurance. It is not, as many suppose, a business for the acquiring of money, in the sense applied to ordinary mercantile affairs. True life insurance is a business of wide philanthropy; and while there are stock companies who find it possible to combine business enterprise and profit with this philanthropy, most companies are mutual, and all excess above the expense of conducting the business and the reserve held for the policy-holder is returned to each member as a dividend. The insurance is properly not for the man insured, but for his family in case of his untimely death. True, various forms of policies are now issued, under demand for investment and the pressure of sharp competition, where the personal interest of the insured is contingent; but the great bulk of insurance is still what it was originally designed to be, a true philanthropy.

Any company so successfully managed that it can return large dividends is deservedly popular. It is returning money not consumed by great mortality nor bad investment.

Competition among companies is strained to the utmost. To attain pre-eminence no scheme is overlooked; no care, no study neglected; and it is probably true that no medical officer of any large company has failed to consider over and over again the probability of profit in prolonging the life of the insured. From the standpoint of economy, from that of extension of benefits and from that of mere advertisement, the subject has been discussed.

The matter of prolonging the life of consumptives has been especially considered, but deemed, in view of the inadequacy of all remedial measures, beyond the province of a life company.

Aside from the business complications and perplexities which will be dwelt upon later, the point strongly urged by Dr. Denison, that money could be advantageously loaned to aid the diseased in going to a proper climate, is already met by some companies, certainly by the Mutual Benefit of Newark, N. J., which will loan liberally upon policies that have acquired a reserve value, to any holder, whether sick or well, at the ordinary rate of interest.

Another point, not only of popular but also of professional error, which the growth of life insurance has corrected, relates to the rate of mortality from consumption.

When the experience of the first thirty years of the Mutual Life (quoted by Dr. Denison) was published, this disease was a source of grave apprehension, but it has long ceased to be so. The application of principles of hereditary susceptibility, the modern doctrine of contagion, the improvement in the general standard of physicians, and the extreme care exercised in the selection of examiners have reduced the mortality from consumption to such a degree, that it bears in the mortality record but a moderate ratio to other diseases. Apoplexy, paralysis, Bright's disease, heart disease, and even the preventable zymotic diseases, are regarded with at least equal anxiety.

After what has been said, it will readily be seen that if a company should undertake to care for its consumptive policy-holders, a flood of inquiries would be made as to why the man suffering from nervous prostration, from heart disease, from the sequelæ of typhoid fever, the results of la grippe, and even the sufferer from business embarrassment to the verge of suicide, should not receive like assistance. The universal complaint would be "unfair discrimination."

If in reply, it could be demonstrated that the other policy-holders were in reality the gainers by such discrimination, all would be well; and we may therefore ask, Would it pay either them or the company? In other words, Is the scheme practicable?

Assume for a moment that it is to be tried: There is first the selection of qualified men as referees, whose opinion is to be relied upon. Over the wide area of the United States alone this would be a task involving much valuable time, travel and expense. There must be enough to be available in every State, and they must be men whom other physicians could look upon as authority.

As they are to be paid by the company, they could not refuse to examine either those hopelessly ill, nor those who having catarrh or bronchitis or debility or dyspepsia, fear they are becoming consumptive. The latter would be numerous, for it is a fact of observation, that the man with an annoying bronchitis or a protracted catarrh thinks he has consumption, while the man actually in the incipient stage is quite sure he has not, and finds many a physician who will assure him that his is but a trifling ailment.

Out of 100,000 policy-holders there would be ten per cent. (10,000), or at a very low estimate five per cent. (5,000), who would seek such free examination from an expert; and at $10, there would be an outlay of $50,000 annually. The correspondence resulting, would require the employment of a competent supervisor and at least one clerk to look after beneficiaries, referees, claims, appeals, reports and advances of money, an outlay of from $6,000 to $10,000 more.

Here then is a total, at a low estimate, of $60,000 annually, not including the expense of travel to settle disputes, the notifying of 100,000 policy-holders, circulars to the newly insured, and the many minor sources of outlay attending a special philantrophy.

As an offset we will assume that the life of seventy-five per cent. of consumptive policy-holders would be prolonged three years — a percentage almost absurd, since not more than twenty per cent. are usually prolonged at all by climate, travel, or the advantages offered to those with money; but place the percentage high, seventy-five.

The percentage who would be finally cured would be too small to enter into the computation. Ten to twelve per cent. of the deaths in a well-managed company is now about the rate from consumption. With 100,000 policy-holders a long established company loses only 150 annually from this disease. These are chiefly in early or middle life. Seventy-five per cent. of this number is 112.

Take, then, the average amount of policies and a high average of premium, and only about sixty per cent. of the first year's outlay would be received by the company in the three years, and of this a very considerable amount would be returned as dividend. This, it must be remembered, is assuming such liberal estimate as experience by no means justifies; and disparity of return for outlay is yet very great.

Setting aside, then, the question whether it would pay (not profit but expenses), a very important question is, Has a company the moral right after insuring a man's life for the benefit of his wife and children, even if the policy is a self and not a wife's policy, to compromise with the insured for his own benefit beyond offering a fair portion of the reserve value as a loan? Is it wise with reference to self-policies, whether life or endowment, to introduce a purely speculative element?

Of course, a man holding a self-policy can usually obtain a surrender value in cash, and the moral feature of the transaction rests with himself; but a systematic attempt to force a surrender or to assume to discount payment upon the chance of fatal issue of disease, whether under the guise of philanthropy or for the profit of the company is quite another matter. Quite certainly it would not be profitable.

While the broadening of the field of life insurance for the general good in the direction discussed can hardly be deemed practicable, there is one direction in

which it may be, that, so far as we are aware, has not been laid before the public; and this is in influencing sanitary legislation.

The advances of modern times made in barring out epidemics from our seaboard, in preventing the pollution of the water-supply of cities, in closing wells and dairies from which the germs of typhoid fever are disseminated, have undoubtedly spared thousands of lives.

We need not specify, perhaps, any particular instance, although it would be easy to do so, since no one now disputes the value of legalized sanitary supervision; but the opposition of politicians, and the obstacles constantly interposed to proper legislation by unscrupulous or ignorant partisans, still hamper and counteract the progress of sanitary science.

Life companies could well afford to have in every legislature one or more competent men alive to the importance of preserving life; and the saving of only one insured person annually from preventable disease would more than cover the cost, and prove of benefit to the whole community.

RELATIONS OF DYSPEPSIA TO PULMONARY TUBERCULOSIS.

AT the recent French Congress for the Study of Tuberculosis recently held in Paris, one of the subjects discussed was that of the relationship of dyspepsia to pulmonary tuberculosis.

Marfan has maintained in his thesis that the digestive disturbances of the phthisical bear the relation not of cause but of effect; in other words, they are but one of the manifestations of the tuberculosis. Often the dyspepsia masks the tuberculosis. Marfan believes the initial dyspepsia to be caused by a "humoral state."

According to Hayem, whose paper attracted much notice, the gastritis of the phthisical is a common gastritis due to the ordinary causes of stomach inflammations. It is generally accompanied with retardation in the evacuation of the stomach and consequently with dilatation. It sometimes precedes for several years the appearance of the tuberculosis, and is only exaggerated at the onset of the phthisis in patients who take excitant drugs or who adopt a regimen not adapted to the state of their stomachs.

The causes of the gastric affections of the phthisical are those of ordinary gastric affections, to wit, the abuse of tobacco and alcohol, errors in diet, etc. It is a mixed gastritis, parenchymatous and interstitial.

In one case, Hayem found, at the autopsy, a general amyloid condition of the entire mucosa; in another, a necrosis due to a thrombosis; exceptionally, he has met with a tuberculous ulcer.

A gastropathy of uncertain source begins early in life; it entails a state of general debility, and at a certain moment pulmonary tuberculosis bursts forth. The physician then institutes an active treatment based on super-alimentation and the abuse of medicaments.

Under the influence of this particular regimen continued for months, there supervene the symptoms of violent gastric catarrh, in other words, the "initial gastric syndrome" of Marfan. It is simply the exaggeration of a gastropathy which had existed for many years, sometimes fifteen or twenty years before the appearance of the pulmonary accidents. Under a suitable dietary regimen and the suppression of medicines these gastric symptoms vanish.

When the attending physician discards the administration of irritant medicines and prescribes nourishing, easily-digested food, he will even in febrile cases see the condition of the stomach improve.

The tuberculosis at the onset, then, does not make the state of the digestive organs evidently worse. On the contrary, there are few diseases which so rarely affect the stomach. One is often astonished at the digestive capacity of the phthisical, who will eat more nutritious food than a well man.

In concluding, Hayem said that with the exception of rare lesions, ulcerations, amyloid degenerations, etc., the gastritis of the phthisical is of the common kind.

It is sometimes latent, and is not diagnosticated before the appearance of the tuberculosis. It should, nevertheless, be a subject of preoccupation by the medical attendant, for this gastritis may end in grave gastropathies, and open the door to pulmonary tuberculosis. In hospital patients it would seem that chronic alcoholism is a frequent cause of gastritis.

One of the best means of warding off pulmonary tuberculosis in the predisposed consists in treating the gastropathy.

The proper medication addressed to the digestive tube may perhaps in some subjects arrest tuberculosis at the onset.

MEDICAL NOTES.

A NEW MEDICAL SCHOOL IN BOSTON. — The trustees of Tufts College have decided to establish a medical department. The new school will be located in Boston, and will be opened next October, to men and women on the same footing. Albert Nott, M.D. is the Dean, and Charles P. Thayer, M.D. the Secretary.

WESTERN RESERVE MEDICAL SCHOOL. — Professor Gad, of Berlin, has been appointed professor of physiology in the medical school of the Western Reserve University, Ohio. The required school term each year hereafter will be eight months.

THE JOHNS HOPKINS MEDICAL SCHOOL. — Johns Hopkins University will open its new medical department next October. The regular course in this school is to be four years, and women are to be admitted on the same footing as men, and on the same conditions; a collegiate degree or evidence of an equivalent education.

A SUICIDAL EPIDEMIC. — An unusually large number of suicides has been reported this summer, both in

this country and in Europe. London, Paris and Hungary are especially afflicted. Many of the cases have had no discoverable reasons for their occurrence. The usual conditions of long-continued, dark, wet weather said to cause an increase of suicides have certainly not been present this year.

A GIFT FROM PROFESSOR CZERNY. — Dr. Czerny has sent a contribution of twenty dollars to the Gross Monument Committee, as a mark of his "admiration for the man and the surgical work which he has done."

DEATH OF A MEDICAL HOUSE-OFFICER. — Another sad case of death during hospital duty is reported from London. Mr. Arthur Durham, a brilliant graduate of Christ's College, Cambridge, and of Guy's Hospital, died August 11th while on duty as medical house-officer at the London Fever Hospital, after an illness of only four days, from virulent diphtheria contracted from a patient.

ADMISSION OF WOMEN TO THE BRITISH MEDICAL ASSOCIATION. — In accordance with a resolution passed last year, the British Medical Association has amended its by-laws granting membership to women-physicians, or as they are called in England "*lady-medicals.*"

MEDICAL PROGRESS. — In a recent valedictory address at Glasgow University, Professor McKendrick summed up the results of the development of medical knowledge during the last thirty years, as follows: "Thousands of lives saved annually by preventive medicine; greater accuracy in diagnosis, and a sounder knowledge of the natural history of disease; more rational treatment; many diseases caused to pass through their stages more speedily, thus saving time; better means of relieving pain and suffering; and making disease, even when incurable, more tolerable, and at last smoothing the passage to the Elysian Fields."

Miscellany.

A MEANS OF RELIEF IN HAY FEVER.

THE capriciousness of hay fever and the occasional relief obtained from an entirely empirical method of treatment warrant the publication of any means which has proved successful, in the hope that it may be of use to some other person afflicted with this annoying and disabling disease.

Ferber, of Hamburg,[1] reports his own case which had been so severe as to necessitate his using a closed carriage all through the summer. His relief was brought about from accidentally noticing that in the winter a coryza was usually accompanied with hot ears which regained their normal temperature when the discharge from the nose was established. He determined to try a reversed order of effect on the hay fever in the summer, and began accordingly to rub his ears until they became red and hot.

It is now the third year that he has been able to lead an endurable existence during the hay fever season. "As soon as the least sensation of fulness in the nose appears, there is recognized a certain amount of pallor in the ears. A thorough rubbing of the ears, at times even to contusion, has always succeeded in freeing the nasal mucous membrane from its congestion. The rubbing, however, must be *thorough* and repeated as often as the least symptom of congestion returns to the nose. Since using this means I have been able to take long sandy walks, sit and even sleep with open windows or pass an evening in my garden without distress. Several patients have had the same relief from this treatment, always in proportion to the thoroughness of the rubbing, and I hope by this means some other physician may be able to give his patients the same great relief."

THE ROTUNDA HOSPITAL REPORT.

DR. SMYLY'S clinical report to the Irish Academy of Medicine of the cases occurring in the Lying-in Hospital of Dublin during the last three years, has some interesting figures. In 3,602 confinements there were but 37 deaths from all causes. Ten of these deaths occurred in the first 1,200 cases, and were due to some form of sepsis. In the last two years no death has occurred from blood-poisoning. There were 107 cases demanding the use of forceps, with a mortality of 29 in the children so extracted. Forty-eight cases of post-partum hæmorrhage occurred, 17 of placenta prævia, and 21 of prolapsed funis.

THE SPACE RELATION OF NUMBERS.

FIXED psychological relations are always interesting subjects of study. The mental association of certain colors and sounds is not uncommon, and the conception of numbers as having a definite space relation is probably more frequent than has been supposed. A case of this primary space idea of numbers in a person taught arithmetic wholly *memoriter* is reported in a recent number of "*Science.*"

The numbers from 1 to 100 are conceived of by the author as holding, relatively, definite positions in space, from which they never vary. This numerical position has no relation with that of any other object or thing, nor with the position of the body or the points of the compass. "The numbers, which are conceived of merely as points or stations in space, appear to be arranged in a peculiar line or lines in a horizontal plane. Beginning with unity, the series runs in a straight line to 20, where it turns ninety degrees to the right, and so goes to 30. Using the points of the compass merely for the present description, and not from any connection with the number-scheme itself, — if the series 1–20 runs (say) northward, 20–30 runs always east, 20 being the apex of the right angle. From 30 to 40 the course is *reversed* and runs back westward; at 40 it again turns at a right angle and proceeds south, without interruption, to 90, where the line again turns east from 90 to 100. Above this point, the numbers have the same positions again. In the mental conception the line 30–40 does not coincide with the line 20–30, but seems parallel to it at some little distance; and a vague sense of space, gradually increasing until no distinct relation is consciously noted, prevents any approach or interference between the numbers above 40 and those below 20."

A CASE OF BILATERAL BRACHIAL PARALYSIS.

A CASE of bilateral traumatic paralysis of the brachial plexuses recently occurred in Bernhardt's clinic in Berlin.

A woman twenty-nine years old, was operated on for a double salpingo-oöphorectomy. During the operation, which lasted for an hour, the arms were held rather forcibly up and back, and shortly after the operation it was found that the woman had a double Erb's paralysis affecting almost identically the same muscles on each side. The infra- and supra-spinatus, the deltoid biceps, brachialis, and both supinators were completely paralyzed; the triceps and pectoralis major were partially so. Sensory disturbances in the skin existed over the areas supplied by the axillary, musculo-cutaneous and some of the branches of the median nerves.

The paralysis was evidently due to the crossing of the clavicles upon the transverse processes of the sixth and seventh cervical vertebræ, thus compressing the plexuses between two bony parts.

A favorable prognosis was given, and improvement followed persistent electrical treatment by galvanization through the supra-clavicular fossa, and gentle faradization of the muscles.

CARCINOMA OF THE ŒSOPHAGUS.

THE number of cases of primary cancer of the œsophagus so far reported is small — under two hundred.

The following case of Axtell's[1] is interesting in that the growth was primary; did not cause secondary infection, and was limited to the œsophagus. The patient was sixty years old and had had good health up to his present illness. There was no history of carcinoma or tuberculosis in the family. In November, 1891, while eating he experienced a peculiar sense of constriction in the epigastrium, which continued thereafter. He was able to take solid food without inconvenience until February, 1892, when he found that he could no longer swallow solid food, even if masticated very finely. If the food were swallowed it would be ejected in two or three minutes, apparently not passing beyond the level of the larynx. From that time he could take only liquid food and in September only in very small amounts.

He then began using the stomach-tube once a day and was able to take a little more nourishment. On passing the tube he could feel it turn on itself. He complained of a pronounced sense of weight, as though something were growing in the larynx. He had no cough, but at times a large amount of mucus would find its way into the throat and cause some inconvenience. An ivory bougie introduced into the œsophagus was stopped at a distance of twelve inches. He died of asthenia thirteen months from the first symptom noticed.

At the autopsy, an annular tumor-mass was found in the walls of the œsophagus one and one-half inches above the cardiac orifice of the stomach at no point more than two inches in vertical diameter. It was hard and nodular and almost completely closed the gullet. A fine probe could be pushed through the small opening without resistance. The mucous membrane over the growth was in a state of ulceration. The tumor-mass was completely isolated. No secondary growths were found anywhere, and the bronchial glands were not enlarged. Sections of the tumor-mass showed a typical scirrhous carcinoma, with small spheroidal cells in the alveoli.

GANGLION.

THE frequency with which ganglion occurs, the disabling annoyance it causes, and the tendency it has to return after the usual treatment by rupture are well known and need no comment. There has been, however, much looseness in the use of the term, and many cases of teno-synovitis have been classed and treated as ganglion. This is unfortunate in two ways. The treatment of a synovitis should be by rest, a ganglion by quite other means; and to confuse the two is to maltreat the patient and spoil statistics of either cases.

Jordan[1] has made a detailed report of twenty-five cases of ganglion recently under his care. He includes in his list only cases of true ganglion, that is, a small cyst connected with the sheath of a tendon and unconnected with any of the more superficial structures; the sac consisting of a fibrous capsule lined with synovial membrane. The cause of the affection he believes to be in almost every case a hernial protrusion of the synovial membrane through a slit in the sheath of the tendon with a subsequent compression of the neck and closure by plastic inflammation from the rest of the synovial cavity.

Of the various methods of treatment none have been so successful as could be desired. Rupture, electrolysis, puncture, excision — all have well-known objections, either an insufficient cure or undue exposure of the tendon sheath to inflammatory action, and obliteration. He has found the most successful results from the aspiration from the sac of ten to sixty minims of the fluid and the injection of the same amount of Morton's fluid without removing the needle. The sac was rubbed to ensure thorough contact, and the hand then put upon a splint and padded, for five days. The previous failures from injection he attributes to too weak a fluid to cause sufficient inflammation, or to so strong a solution that it becomes surrounded by a layer of coagulated lymph before it touches the walls of the sac itself.

Of his cases twenty-three occurred in women — of whom seventeen were washerwomen or house-servants who have hard manual work to perform, and a considerable amount of "wringing" to do — the very kind of work that would be likely to lead to a hernia of the synovial membrane. Twenty of the ganglia occurred on the tendon of the extensor communis digitorum, one each on the extensor carpi radialis longior, extensor communis digitorum, extensor secundi internodii pollicis, peroneus longus and flexor longus pollicis.

The duration of the affection had been from six weeks to six years. The average amount of fluid withdrawn was thirty-eight minims, and of the injection about twenty. Several of the cases had been ruptured or otherwise treated before. None suffered any discomfort and all were reported well, with no return after the end of twenty-one months.

THERAPEUTIC NOTE.

SALOPHEN IN ACUTE RHEUMATISM.—Hardenberg[1] reports ten cases of acute rheumatism treated with salophen, and sums up his observations as follows: "A fifteen-grain dose every three or four hours for twenty-four hours is frequently sufficient. In no case was there observed any toxic effect or gastric or aural irritation. The average febrile period was but six days, and the average total stay in the hospital but ten days. The pain was quickly relieved and no cardiac complications followed." These conclusions are in all respects in accord with the observations of Caminer[2] and Froehlich[3] and the later reports of Osswald[4] and Koch,[5] all of whom found in the pleasanter taste of the drug an advantage over the salicylates. In cephalalgia, pleurodynia and some cases of trigeminal neuralgia marked relief was obtained from small doses. In the severer cases of acute rheumatism, however, the German observers looked upon salicylate of sodium as still the best remedy. Drasche and Hoischmann both report cases of the elimination of the drug by the skin in a crystalline form exactly like the crystals of the original powder. If this is true, it throws doubts upon the supposed splitting up of salophen into a salicylate and a phenol in the system. The remedy is best given in powders.

Deaths reported 3,445: under five years of age 1,719; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 1,021, diarrhœal diseases 742, consumption 309, acute lung diseases 187, diphtheria and croup 105, typhoid fever 72, whooping-cough 28, cerebro-spinal meningitis 27, scarlet fever 20, malarial fever 13, measles 12, erysipelas 2.

From whooping-cough New York 7, Philadelphia 6, Chicago and Brooklyn 4 each, Washington 2, Boston, Cincinnati, Cleveland, Milwaukee and Cambridge 1 each. From cerebro-spinal meningitis Chicago 13, New York 5, Lowell 3, Washington 2, Philadelphia, Worcester, Somerville and Quincy 1 each. From scarlet fever New York 5, Milwaukee 3, Chicago, Philadelphia, Brooklyn, Boston, Cleveland and Malden 2 each. From malarial fever New York 6, Brooklyn 3, Boston, Cleveland and Nashville 1 each. From measles New York 6, Brooklyn 3, Philadelphia 2, Milwaukee 1.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending August 5th, the death-rate was 21.9. Deaths reported 4,344; acute diseases of the respiratory organs (London), diarrhœa 695, whooping-cough 115, measles 85, diphtheria 77, fever 67, scarlet fever 66, small-pox (London, West Ham and Bradford 3 each, Birmingham and Salford 1 each) 11.

The death-rates ranged from 14.8 in Croydon to 34.1 in Preston; Birmingham 22.2, Blackburn 20.9, Bradford 22.6, Gateshead 20.6, Leeds 22.2, Leicester 21.7, Liverpool 30.8, London 20.8, Manchester 23.8, Newcastle-on-Tyne 18.3, Nottingham 18.4, Oldham 19.8, Sheffield 24.7.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending August 12th, the death-rate was 20.9. Deaths reported 4,136; diarrhœa 604, measles 89, diphtheria 82, whooping-cough 76, fever 67, scarlet fever 47, small-pox (Salford 3, London and West Ham 2 each, Manchester and Bradford 1 each) 9.

The death-rates ranged from 12.9 in Croydon to 24.1 in Preston; Birmingham 20.3, Bradford 19.8, Hull 23.2, Leeds 22.5, Leicester 18.0, Liverpool 25.4, London 19.6, Manchester 23.9, Newcastle-on-Tyne 19.3, Nottingham 17.5, Sheffield 27.8, Sunderland 25.6, West Ham 16.1.

METEOROLOGICAL RECORD,

For the week ending August 19, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Barometer	Thermometer.			Relative humidity.			Direction of wind.		Velocity of wind.		We'th'r.*		Rainfall in inches.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 19, 1893, TO AUGUST 25, 1893.

Board of officers to consist of COLONEL CHARLES H. ALDEN, assistant surgeon-general; LIEUT.-COL. WM. H. FORWOOD, deputy surgeon-general; MAJOR JOSEPH K. CORSON, surgeon, is, by direction of the Secretary of War, appointed to meet at the Army Medical Museum Building, Washington, D. C., Monday, September 4, 1893, for the examination of such officers as may be ordered before it, to determine their fitness for promotion.

By direction of the Secretary of War, a board of medical officers, to consist of COLONEL CHARLES H. ALDEN, assistant surgeon-general; LIEUT.-COL. WM. H. FORWOOD, deputy surgeon-general; MAJOR CHARLES SMART, surgeon; CAPTAIN WALTER REED, assistant surgeon, and CAPTAIN JAMES C. MERRILL, assistant surgeon, is constituted to meet at the Army Medical Museum Building in this city, on the 11th day of September, 1893, for the examination of candidates for admission to the Medical Corps of the ARMY. Par. 1, S. O. 193, Hdqrs. of the Army, A. G. O., Washington, August 23, 1893.

By direction of the Secretary of War, the following named medical officers are detailed to represent the Medical Depart-

ment of the Army at the Pan-American Medical Congress to be held in Washington, D. C., September 5 to 8, 1893: Colonel B. J. D. Irwin, assistant surgeon-general; Lieut.-Col. Dallas Bache, deputy surgeon-general; Major David L. Huntington, surgeon; Major Charles Smart, surgeon.

Lieut.-Col. Wm. D. Wolverton, deputy surgeon-general, is relieved from duty at Watervliet Arsenal, N. Y., and assigned to duty as medical director, Department of the Columbia, to relieve Lieut.-Col. C. C. Byrne, deputy surgeon-general, U. S. A.

Lieut.-Col. C. C. Byrne, deputy surgeon-general, on being relieved from duty as medical director, Department of the Columbia, will report for duty as medical director, Department of Dakota, to relieve Colonel Charles H. Alden, assistant surgeon-general.

Colonel Charles H. Alden, assistant surgeon-general, on being relieved from duty as medical director, Department of Dakota, will proceed to this city and report to the surgeon-general, U. S. A., for duty in his office and as president of the Army Medical School, Washington, D. C.

Leave of absence for one month, with permission to apply for an extension of ten days, is hereby granted to Captain J. L. Powell, assistant surgeon, U. S. A.

Leave of absence for one month, to take effect upon the return of Assistant Surgeon Glennan from leave, is granted Captain Wm. F. Carter, assistant surgeon.

Major Justus M. Brown, surgeon, is relieved from duty at Fort Meade, South Dakota, and assigned to duty at Fort Wayne, Michigan.

Leave of absence for one month, to take effect about September 1, 1893, is granted Captain Paul Shillock, assistant surgeon (in the field), with permission to apply for an extension of fifteen days.

The commanding officer, U. S. Troops, in the field near Fruitland, N. M., is authorized to employ a citizen physician in cases of necessity during absence of Captain Paul Shillock, assistant surgeon.

Leave of absence for one month, to commence about September 1, 1893, is granted Captain M. W. Wood, assistant surgeon, U. S. A.

By direction of the Secretary of War, the following named officers will report in person to Colonel C. H. Alden, assistant surgeon-general, president of the examining board appointed to meet at the Army Medical Museum Building, September 4, 1893, for examination for promotion, all assistant surgeons: Captain Curtis E. Price, Captain E. T. Comegys, Captain Walter Reed, Captain James C. Merrill.

Leave of absence for one month is granted Captain R. J. Gibson, assistant surgeon, U. S. A.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 26, 1893.

D. Bloodgood, medical director, placed on Retired List, August 20, 1893.

Geo. F. Winslow, surgeon, from "Monterey" and to the "Philadelphia."

A. A. Hochling, medical director, President of Board to examine applicants for Naval Academy.

G. T. Smith, passed assistant surgeon, from "Baltimore" and to "Wabash."

R. M. Kennedy, passed assistant surgeon, from "Wabash" and to the "Baltimore."

L. H. Stone, assistant surgeon, from Naval Hospital, New York, and to the "Minnesota."

J. E. Page, assistant surgeon, from the "Minnesota" and sick leave for three months.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE EIGHT WEEKS ENDING AUGUST 5, 1893.

Fessenden, C. S. D., surgeon. To proceed to Mobile, Ala., for duty. June 16, 1893. To proceed to New Orleans, La., as inspector. August 1, 1893.

Murray, R. D., surgeon. Granted leave of absence for seven days. June 21, 1893.

Vansant, John, surgeon. To proceed to Wilmington, N. C., for duty. June 16, 1893.

Austin, H. W., surgeon. To inspect Delaware Breakwater Quarantine Station. July 22, 1893.

Gassaway, J. M. surgeon. To proceed to Detroit, Mich., and Chicago, Ill., as inspector. July 12, 1893.

Irwin Fairfax, surgeon. Detailed for duty in office of the United States Consul, London, Eng. July 2, 1893.

Carter, H. R., surgeon. To proceed to Brunswick, Ga., for temporary duty. June 28, 1893.

Peckham, C. T., passed assistant surgeon. Granted leave of absence for six days. June 22, 1893.

Brooks, S. D., passed assistant surgeon. Granted leave of absence for three days. June 22, 1893.

Carrington, P. M., passed assistant surgeon. Detailed for duty in office of United States Consul, Bremen, Germany. June 15, 1893.

Kinyoun, J. J., passed assistant surgeon. To rejoin station, Washington, D. C. July 10, 1893. To inspect Camp Low, New Jersey. July 29, 1893.

Goodwin, H. T., passed assistant surgeon. Granted leave of absence for three days. June 12, 1893. To proceed to Louisville, Ky., for duty. July 12, 1893.

Vaughan, G. T., passed assistant surgeon. To proceed to Chicago, Ill., for temporary duty. July 10, 1893.

Geddings, H. D., passed assistant surgeon. To proceed to Delaware Breakwater Quarantine for duty. June 30, 1893.

Perry, J. C., passed assistant surgeon. To proceed to Portland, Me., for temporary duty. July 8, 1893.

Stimpson, W. G., assistant surgeon. Detailed for duty in office United States Consul, Glasgow, Scotland. July 7, 1893.

Gardner, C. H., assistant surgeon. Granted leave of absence for fourteen days. July 19, 1893.

Strayer, Edgar, assistant surgeon. To proceed to Vineyard Haven, Mass., for temporary duty. July 8, 1893.

Oakley, J. H., assistant surgeon. To proceed to Wilmington, N. C., for temporary duty. June 24, 1893.

Norman Seaton, assistant surgeon. Granted leave of absence for three days. July 24, 1893.

Branham, J. W., assistant surgeon. To proceed to Brunswick, Ga., for temporary duty. July 25, 1893.

Sprague, E K., assistant surgeon. Granted leave of absence for fifteen days. July 22, 1893.

Prochazka, Emil, assistant surgeon, Relieved from duty at Ellis Island, N. Y., and ordered to report to medical officer in command, New York, N. Y. July 29, 1893.

CORRECTION.

In the paper entitled "A Case of Acute Septicæmia," in the Journal of August 17th, on page 170, line 24 from the bottom of the first column, the words "with *the usual* amount of acute irritation," should read "with *an unusual* amount, etc."

RECENT DEATHS.

Dr. Antoine Blanche, the distinguished French alienist, died at Autenil, August 15th.

Mr. Francis Carr Beard, died in London, August 11th, aged seventy-eight years. He was a physician well known in literary circles, having been the adviser and intimate friend of both Charles Dickens and Wilkie Collins.

J. W. Branham, M.D., assistant surgeon in the Marine-Hospital Service, died of yellow fever at Brunswick, Ga., August 20th, aged twenty-five years.

Lectures.

LECTURES ON SURGERY.[1]

BY DAVID W. CHEEVER, M.D.,
Professor of Surgery in Harvard University.

XV.

INJURIES OF THE HEAD.

I am well aware that this lecture is nothing but the outline of a great subject; and it would be impossible to do it justice in an hour. Perhaps it would be impossible for me to do it justice at all; but what I want to do is to give you a plain description of essentials, so that you can work up the subject for yourselves.

No injury of the head can be considered trivial, because the most simple one may lead to fatal consequences. Why that is so is most simply explained by considering the close connection between the contents of the cranium and the outside. We have on the surface a very loose covering over the skull; quite thin skin; very little cellular tissue; a slipping fascia attached to the occipito-frontalis muscle, and a pericranium or periosteum, and then the bone. The bone is not solid. It has a tough outer table. It is permeated with vessels through the centre; and the inner table is brittle and glass-like. Then we come directly to the dura mater, which is attached to the inside of the skull, and really performs the function of an inner periosteum and nourishes the bone. You know with what difficulty it is stripped off from the inside of the skull. The dura mater, however, differs from the periosteum in the fact that it is a fibro-serous membrane; and, consequently, it is very prone to inflammatory changes. You know the delicacy of serous membranes; the rapidity of their circulation; how easily they become irritated and throw out an excessive amount of serum; how, as in the pleural, or peritoneal cavity, that serum changes to fibrin, lymph or into pus. The inner surface of the dura mater, which is serous, forms a cavity called the arachnoid, a serous pocket, which supports the brain, and runs in various directions; and at the inner side of that, we have a close, glistening, vascular layer called pia mater; and then we come to the brain itself. Therefore while the brain is pretty well protected from external blows from the hardness of its envelop, yet it is not as if it were provided with a shell which had no connection with the outside world. It is closely connected by vascular connections, and also by the two layers of its nutrient membrane, dura mater and pericranium.

The simplest form of injury received outside of the skull may lead to trouble inside. A person may receive a scalp wound which does not injure the bone, but it may suppurate inside the dura. The suppuration may easily penetrate and burrow beneath the fascia of the occipito-frontalis muscle. It denudes the bone of its periosteum; leads to necrosis of the bone, the outer layer. There may follow phlebitis and plugging of the little veins of the diploe; transmission of the septic material through the diploe and the inner table; and, often, affection of the dura mater and its serous lining; and that means meningitis and all its consequences. The same thing may follow from a blow upon the head which has not broken the scalp, but has slightly bruised the bone and periosteum, and which may lead to subsequent periostitis with suppuration; necrosis, and exactly the same consequences. We expect of course that when a person receives a blow upon the skull severe enough to fracture the bone, that this envelop having been cracked through, an entrance has been offered to any sort of septic material which may be the cause of disease; but this may also be the case after the slightest possible forms of injuries. I think I have said enough to show that a slight fall upon the head, a slight blow upon the head, may, in a sensitive subject transmit the effects of violence to the brain with great rapidity, and with septic consequences. In addition to this you must remember that inside of the skull is the brain, reposing, to be sure, on a water-bed, and prevented, as far as possible, from jars, by the interposition of water, and of tough membranes called the falx and tentorium, which line it off as it were; and separate one part from another; preventing the jar of one portion from being transmitted to another; so that it is protected as far as possible; yet in spite of all this, the delicate tissue is liable to be shaken up and jarred by any violent fall, or blow upon the skull itself.

The simplest form of injury that the brain substance can receive is temporary, and is called concussion; shaking up. Old authors made a great distinction between concussion and compression. They attempted to classify as concussion everything which did not result directly in pressure on the brain followed by coma, stupor and paralysis. But we now know that this distinction was too nicely drawn; and that between simple concussion and real compression there are three or four intermediate stages, that sometimes are very disastrous in their consequences; and which, frequently, can be distinguished from one another.

We confine now the term concussion to a condition like the following: the patient falls; is temporarily stunned; that is to say, the brain is so shaken up that for the moment it loses its functions. Temporary unconsciousness ensues; the patient becomes pale; the pulse flickers a few moments. Phenomena very like syncope ensue. In a few minutes he rouses; is dizzy; gets up; regains consciousness slowly; has a certain amount of nausea; and then, afterwards, for the rest of the day, or for a short time, has headache, and the trouble is over. That is the simplest form of concussion. It is followed by no appreciable lesion. It is as if we had dropped some delicate instrument, like a watch, upon the floor, and temporarily stopped the works. Picking it up, and giving it a little shake, sometimes the watch will start on as if nothing had happened. So with the brain; and if such a case should be examined at the time, undoubtedly we could find nothing in the brain itself, left behind as a trace of the injury. That is, there is no real lesion.

On the other hand, the patient may receive a like injury, but a little more severe, and instead of recovering consciousness at once, may continue insensible for some little time; and only regain consciousness, perhaps, after some hours, when he slowly returns to consciousness; is sleepy; stupid and pale, and bathed in perspiration; has nausea, perhaps, for another day, and then slowly and gradually comes out of this condition, without any appreciable lesion, and recovers perfectly. That is the second stage, so-called, of concussion. In that case concussion has been followed by a moderate amount of effusion of serum in the ventricles

[1] These are unwritten lectures printed from the stenographer's reports. Verbal corrections are made in revision, but no rhetorical changes. They were delivered to the third and fourth classes as part of the regular course.

and in the arachnoid cavity, producing temporary compression, of short duration; it is speedily absorbed again, and the patient is restored to health.

Another degree still more severe is this: the patient goes through the same phenomena; they last much longer; instead of getting well in a day he gets well in a few weeks, or more. During this time he has positive symptoms of compression of some part of the brain, followed by slight local paralyses; and then, after a while, he recovers even from these. In that case the concussion has been followed by the rupture of some small vessels and by effusion of blood; which blood has coagulated; has compressed limited areas of the brain; has been slowly absorbed, and the patient has recovered.

And finally, there is a stage of concussion which is extremely common and whose symptoms are very peculiar, and which is called, sometimes, concussion with contusion of the brain. In other words, the brain is bruised. The patient receives a blow; goes through the usual phenomena of unconciousness for a short time; rouses from the supposed concussion. There is no paralysis left; but there is high temperature; there is a general irritable condition of the special senses: acute hearing; disagreeable sensibility to light; pupils usually contracted; and frequently one contracted a good deal more than the other; irregular pupils; restlessness; want of sleep; general nervous exitement without positive delirium; this condition coming on for a week, or more; then being followed by severe symptoms of fever; by a chill; by paralysis and by death. In these cases we have what is called concussion of the brain, with contusion or bruising.

First, the shaking up; then the shaking up that went so far that it lacerated some part of the brain. Now, where is that most likely to occur? Obviously if we look at the inside of the skull we must see that that is more likely to occur somewhere about the base of the skull; about these numerous irregularities of the fossæ of the base of the skull. Accordingly the contusions of the brain are generally found somewhere toward the base of the brain; and the symptoms produced, of course, vary according to the particular part of the nervous centre that is injured. These contusions often are of extremely limited extent; and a careful watch sometimes has to be made for them at the autopsy to find where the mischief has been. We do not find a large softened spot of brain; and do not find, perhaps, any large effusion of blood; but search shows, that in certain places, what are called miliary extravasations have taken place. I mean by miliary extravasations the same minute points that we mean when we speak of miliary tubercles in the lungs. Little clots; little softenings; little tumors; capillary bleedings which give rise subsequently to gradual arrest of the circulation of the part from pressure; and afterwards to softening of the substance of the brain; and to minute abscesses, followed by coma and death.

When a man is knocked over, gets up and goes about his business and feels no great disturbance except slight headache, he has been stunned, and has had a slight concussion of the brain. Anything beyond that is almost always accompanied by some permanent lesion; one that will last for hours, or days, or longer. In the simple cases, effusion of serum; in the more severe class of cases, effusion of blood; and in the severest class, bruising of the brain substance itself.

Now, on the other hand, when a person, for instance, receives a blow from a club in the hand of some other person upon the top of the head, and is knocked down in consequence, a scalp wound may be produced; in which case we wash away the blood and look at it, and find a large piece of the skull driven in; never driven in squarely; but compressing the brain substance itself. Such a piece of bone, if raised, is frequently found to have torn the dura mater; and it not infrequently happens, when we first see the patient, that we find portions of cerebral substance oozing from out of the chink where the bone has torn through the dura mater and lacerated the brain itself. Such a patient is felled unconscious, but he never rouses. As long as he is untreated, he never rouses. That is true compression of the brain. A blow which has knocked in the skull, lacerated the dura mater, crushed the brain substance and interfered permanently with the function of the brain by pressure is called compression. A case so marked as this gives very marked symptoms; and quite distinct from the symptoms of the various degrees of concussion that we have mentioned. Such a patient has dilated pupils, which are wide open and will not respond to light. He snores in respiration, just as a patient does under the profound anæsthesia of ether. He sweats profusely. His pulse is extremely slow and full and labored; sometimes sinking as low as fifty, forty-eight, forty-five or forty, or even thirty beats a minute. It is regular, and full and bounding; but extremely slow. He is practically dead to consciousness. He is unable to swallow; unable to rouse; does not use his limbs; is perfectly unconscious. This condition, if not interfered with, terminates in death, but not immediately. The patient lasts quite a while; generally into the second day; sometimes a few hours; but usually thirty-six to forty-eight hours, before he gradually sinks and dies, with an interrupted, sighing respiration, without the slightest return of consciousness. This is pure and distinct compression. Between such a state as this and the condition of a patient temporarily stunned, who is quickly roused; with flickering pulse; irregular pupils; nausea, etc.; the distinction is extremely marked. Simple concussion, the lighter degrees, are usually distinct from those of pure compression; and it is only when we come to cases of concussion of the third and fourth classes, where there has been a lacerated blood-vessel, or bruised brain, that the symptoms begin to run together, and it is difficult to tell the symptoms of concussion with contusion from those of compression itself. I speak of this more particularly because in the older books on surgery a distinction was made between concussion and compression. Concussion was so-and-so; compression so-and-so, as if all cases of head injury which were at all severe could be classed at once as simple concussion, or profound compression; whereas they grade into each other; the condition of the pupils now has come to be less and less regarded as diagnostic of one from the other. The most important prognostic point about the condition of the pupils, which seems to have been brought out by late investigations, is whether or not they will respond to light. If they respond to light, a large percentage rouse and recover; if they do not respond to light, a very large majority never rouse from the condition of coma. The patient may be unconscious; and yet the pupil, if a bright light is thrown on, may act, or may not act; and that seems to give us a very important guide as to the future of the case.

When the concussion is accompanied by effusion of serum, it is poured out about the seat of the injury in the arachnoid cavity. This also distends the ventricles, adds largely to the amount of cerebro-spinal fluid, and makes a temporary serous apoplexy as it is called, temporary serous compression. This does not last long. It is soon absorbed and goes away. It would be hardly worth while to inquire where such an effusion of serum probably begins. It soon becomes diffused, and its symptoms, which are produced in a few minutes, seem to be about the same no matter where the first blow was received. It is absorbed again and its symptoms pass off. Not so with the effusion of blood. It makes an immense difference where the effusion of blood starts from. After a blow received upon the head which ruptures a vessel inside the skull, blood may be poured out in quite a variety of situations according to the vessel that was wounded. In the first place, it may be between the dura mater and the skull; in which case it is very distinctly localized; and cannot be poured out very rapidly. It has to dissect up the dura mater from the skull itself; slowly tearing away the membrane from the bone; and by the hydraulic pressure of the pumping vessel a clot is slowly formed between the skull and the dura mater; it coagulates, and separates the membranes from the skull.

On the other hand, the effusion of blood may take place inside the cavity of the arachnoid. The vessels may be ruptured there. In that case the hæmorrhage goes on rapidly. There is nothing to arrest it, nothing to localize it or determine where it shall go except the thousand accidents which may come from the position of the patient, the side on which his head lies. The effusion of blood in the arachnoid cavity rapidly diffuses itself in any direction according to the laws of gravity, and ceases to be localized very soon after the vessel is ruptured.

Not so from the laceration of deeper vessels about the base of the skull, which result from a tear of a nutritive vessel permeating the brain substance itself. These must be localized. They form local clots; their phenomena resemble those which follow an ordinary attack of apoplexy, where one of the nutritive vessels in the brain bursts and a clot is poured out; is localized; pushes aside brain tissue; cannot become very large, and the symptoms produced are due to the loss of function of that particular spot of the brain where it occurs, and the part of the brain which it happens to compress.

In old times, Mr. Pott, an eminent surgeon in London, wrote a book on trephining the skull for injuries of the skull and lacerations of vessels, in which he thought he could determine the place where the vessel was ruptured, trephine and remove the clot, and relieve the symptoms and cure the patient; and for a certain percentage of cases he did so; but it so happened that, in all probability, the larger proportion of Mr. Pott's cases were those of extra-dural hæmorrhage; that is, between the dura and the bone. The vessel most likely to be ruptured there is the middle meningeal artery, which passes up behind the inner side of the temporal bone, one and a fourth inches behind the outer angle of the orbit. A blow being received in that vicinity, if it ruptured a vessel inside the skull, is more likely to rupture the middle meningeal artery than any other. A blow on the squamous portion of the temporal bone is likely to crack through that bone and to rupture the middle meningeal artery. Probably a good many of Mr. Pott's cases were rupture of the middle meningeal artery. The effusion was localized; was directly beneath the site of the blow. The bruise on the scalp, or the cut on the scalp, led to the location of the clot inside the skull. On trephining he found the clot; removed it, and the patient was relieved.

On the other hand, we have no guide as to the location of effusions of blood in the arachnoid cavity. They are poured out, diffuse themselves, may go anywhere within the arachnoid cavity. The coagulations, however, which take place in the brain substance, from rupture of a vessel there, produce as distinct and permanent a class of paralyses as the various forms of apoplexy, and can be localized better.

Perhaps it is well, in this connection, to point out to you the very great distinction which exists in the rapidity of the symptoms that are produced between compression caused by a piece of bone driven down upon the brain, and compression caused by extravasation of blood between the dura mater and brain from a tear of the middle meningeal artery, or from some other vessel between the skull and the dura mater. Take the patient who is knocked down we will suppose with an axe; the skull driven in; he is instantly felled and unconscious; lies comatose — this is an example of compression. On the other hand, the patient who has received a blow rupturing one of the extra-dural vessels goes through the following series of phenomena. At first he is stunned; he rouses from that; after lying a few moments he is able to get up; feels dizzy and uncertain; but retains consciousness; and is frequently able to walk; grows better for some little time; and it is only after the lapse of a half-hour, or hour, that he begins to feel a sense of terrible weight and stupor in the head, and gradually becomes more and more dizzy, until finally he drops into a state of paralysis and unconsciousness and compression. This arises from the gradual effusion of blood which is poured out with great force between the dura mater and the skull; dissects the dura mater from the skull in proportion to its size; must compress the brain, because the skull cannot yield, and the dura mater and brain can.

Compression from hæmorrhage inside the skull is gradual; compression from the driving in of bone is immediate. Those are the general distinctions between the two.

All the phenomena of head injury, however, as regards the point where the blow was received, and the consequent injury, are very much modified and confused by another force which comes into play, and which is called contre coup; that is, transmitted force to the opposite side of the skull. Hence effusion of blood and the phenomena of paralysis may be all due to an injury at a point directly opposite the point at which the blow was received. This, of course, confuses very much the diagnosis and prognosis of brain injuries.

We hear a good deal of fractures of the base of the skull. They are various in character. There are certain parts at the base of the skull which are quite thin and which more readily break than others. Those are called fossæ. We have the anterior, middle and posterior cerebral fossæ. The anterior cerebral fossa is formed by the roofs of the orbits which are extremely thin; and it is bounded by the glenoid process of the sphenoid bone, which separates it from the next, the middle fossa, which is quite thin. This is bounded by

the firm structure of the petrous portion of the temporal bone. Then we have the posterior fossa where the occipital bone is quite thin down by the foramen magnum, bounded by the temporal bone in front and the thick occiput behind; and it is thin also over the venous sinuses at the base of the brain.

Fracture of the base of the skull is difficult to diagnosticate, because we cannot see anything; can trace nothing; can feel nothing about the skull. The injury is where we cannot trace the fractured bone, or be guided by any of the ordinary signs; and can only infer and reason from symptoms, where, probably, a fracture of the base has taken place, if it has taken place at all. The patient may be in a state of compression, and yet there may be no evidence of depression of bone upon the surface of the skull. The question then arises whether this compression may be due wholly to laceration of brain and formation of clots, or whether it is accompanied also by fracture of the bone, out of sight, in the base of the skull. It is sometimes difficult to distinguish between the two. There are certain phenomena which show themselves outside which enable us to judge to a certain degree; and these phenomena are quite important. In fracture of the anterior fossa of the base of the skull, we have the roofs of the orbit cracked through more or less; have the cribriform plate very easily cracked through; and occasionally we have also an opening forward into the frontal sinus; but, at any rate, the cribriform plate, or the roof of the orbit, is almost sure to be broken through. Two series of phenomena follow: nose-bleed coming from the cribriform plate, from the rupture of veins there; and the other is what we call subconjunctival ecchymosis, ecchymosis not in the ordinary form of black eye which breaks the vessels of the lid or conjunctiva, but bleeding which takes place beneath the conjunctiva, and spreads itself over the sclerotic coat of the eye. This is due to the rupture of vessels deep in the orbit. In severe cases this blood may extend, if the crack through the orbit is extensive, may extend elsewhere, and gradually the patient will exhibit discolorations upon the face and neck, several days after the injury, the face becoming black-and-blue in extreme cases. Ordinarily, we have nose-bleed and ecchymosis in the orbit.

Now, on the other hand, if the middle fossa is broken through, the most likely place where blood will be poured out is into the throat and mouth. The top of the pharynx is attached at the junction of the spheno-occipital bone; and hence bleeding into the mouth and throat is not uncommon in consequence of fracture of the middle fossa of the base of the skull. Inasmuch as the petrous portion of the temporal bone is so near, frequently we have lacerations which extend through the middle chamber of the ear, and cause bleeding from the ear itself. Bleeding from the ear, and serous discharge from the ear, have long been considered among the most significant symptoms of fracture of the middle fossa of the base of the skull. They are not, however, diagnostic. The bleeding from the ear is quite common in severe injuries of the head, and does not necessarily mean any injury of the bone. Any small vessel may be ruptured and bleeding take place. Neither does the discharge of serum from the external ear, unless very profuse in quantity, necessarily mean fracture of the middle fossa about the base of the skull, and the leaking of cerebro-spinal fluid. When profuse and long-continued, then it can be nothing but cerebro-spinal fluid which runs out through the fracture of the middle fossa at the base of the skull and the laceration of the membranes; it is increased in quantity by the irritation of the injury, just as we see in other cases where an injury has been received, and it is poured out in large quantities. This, however, is extremely rare. When it is seen, it is a diagnostic symptom of fracture of the middle fossa of the base of the skull.

When, however, the serous fluid is only seen slightly, for a short time, doubtful, mixed with blood, it may mean nothing more than the liquid contents of the vestibule and labyrinth which have leaked out through the fissure of the drum, and possibly the partial fissure of the temporal bone, which may not extend inside of the skull to the cavity of the brain.

One other symptom, however, may arise in this connection, which is very characteristic, and that is facial paralysis. Facial paralysis, if it occurs in connection with these other symptoms, is almost diagnostic of fracture of the middle fossa of the base of the skull, because it shows that the petrous portion of the temporal bone has been broken through, that the facial nerve has been compressed in its bony canal, and facial paralysis is the direct consequence.

In the posterior fossa we also have laceration into the ear. We have also other symptoms; we may have bleeding into the pharynx, the same as in the middle fossa. We have one other symptom, quite diagnostic sometimes, and that is a break through the lateral sinus, and effusion of blood in and behind the mastoid process, and out in the neck; large ecchymoses gradually forming behind the ear, and running down the back of the neck. These are very marked; and indicate, almost invariably, rupture of the lateral sinus with leaking out of venous blood into the tissues behind the ear, behind the mastoid process, and down between the long muscles of the neck.

Nose-bleed, subconjunctival ecchymosis, bleeding in the pharynx, blood and serous discharge from the ears, facial paralysis, large ecchymoses behind the mastoid process — those are the common phenomena accompanying fracture of the base of the skull.

Fracture of the base of the skull can hardly occur without cerebral laceration and some effusion of blood within the skull itself; therefore the symptoms are almost always of the mixed variety. There may be complete unconsciousness. There may not be. It depends upon the amount of compression. If the patient lives, the case is a long one to recover. Some of them do recover. It sometimes is a long one, if it has a fatal result; and fracture of the base of the skull is occasionally followed by a prolongation of life for a week or ten days, during which the patient finally sinks, with symptoms of cerebral abscess and softening.

One great danger that arises in injuries of the head is from the occurrence of septic absorption from some of the wounded tissues. This, of course, is especially the case in wounds which communicate with the air, and in compound fractures. That danger, and the danger of injury of the brain and membranes by fragments of bone, is the next point we have to speak of.

Now the only way that we know of averting the dangers of sepsis and pressure is by surgical interference. Surgical interference in the skull means generally the use of the trephine, because otherwise we cannot get at the injured parts. It is true that occasionally a fracture of the skull occurs which is so comminuted

that we have only to press away the periosteum and flesh, to pick out certain loose pieces of bone, and we need no further instrumental interference; but usually the bone is driven in under the sound portion, shelved in under the edge obliquely and fastened there, so that it is impossible to extract it. In order to extract it and relieve the pressure, we have to cut out a button of adjoining bone to get room to insert forceps to remove it.

As little of the sound bone is to be cut away as possible; but the centre of the trephine, of course, must be started on the sound bone, and a piece cut out which includes a little more than one-half the circumference on the sound bone, and the rest on the depressed fracture. That is the usual rule.

Such a thing being fully accomplished, and the piece taken out, then the parts are thoroughly cleansed, and dressed antiseptically, as in an ordinary wound. Sometimes a drainage-tube is put in.

But the most important question for us to consider, and one that is yet not fully settled, is, when it is best to interfere at all. In old times trephining was a very different thing from what it is now. It is not too much to say, I think, that the introduction of the aseptic method has diminished the danger, and the mortality from trephining very much. Before the antiseptic method the mortality from trephining was great; so much so that many were discouraged from interfering; and we abstained from using the trephine, if we could find a proper excuse to do so. Now, under the additional safety of the antiseptic method, the tendency has perhaps gone too far the other way; and the tendency of the times is to use operative interference in perhaps more cases than is really necessary.

For a clear understanding of the matter it will be best to proceed in this way: — What cases, in the first place, should be trephined under any method of practice; demand trephining? First, punctured, depressed fracture. Some little hard substance, like a bit of iron or sharp piece of steel or portion of a block from a ship, falls from a considerable height, strikes the patient squarely on top of the head, produces a minute punctured scalp wound, also a minute punctured wound of the skull, exactly as if a nail had been held against the skull and driven in with one blow of the hammer. At first the patient undergoes the usual phenomena of a temporary concussion; he falls and is unconscious, but soon comes out of that; and, subsequently, he frequently gets up, and often walks to the hospital; and comes in to have a simple scalp wound dressed, not feeling that he is deeply hurt, and not willing to believe it. The symptoms which are produced by this injury are not immediate; and unless we knew, by experience, what was going to follow in all these cases, after a few days, if let alone, we should not feel called upon to interfere with the patient at all. But the subsequent history is this: the outer table being broken through in a minute hole, the inner table is also depressed and shivered into fragments; and although the outer table may be in one piece, the inner table is almost always in several pieces; minute and detached and sharp fragments, which press in on the dura mater, and surely set up meningitis. They do not at first make sufficient compression to make the patient sick; but in a few days he begins to be sick; symptoms of meningitis come on; and then the little pieces, which are detached and unnourished, necrose, and continue the suppurative process, and set up septic phenomena in addition to the ordinary ones of inflammation of the meninges; and the result is almost inevitably fatal. Such patients have, at first, but few symptoms except the immediate effect of the concussion; have a little headache and dizziness and do not feel much sick. If not treated, in a few days this series of phenomena begins to come on: the patient begins to grow a little restless, uneasy, a little sensitive to light, a little acute about hearing sounds, begins to have persistent headache; his temperature rises, and presently are ushered in the symptoms of acute inflammation of the membranes. Here is a case where trephining is called for at any rate. The patient must be persuaded to submit to it; and a cure, at such an early stage and with so slight an injury of the parts, is pretty sure to be produced; but even if it were not sure to be produced, we should persuade the patient that he should be trephined, on account of the subsequent history, which is sure to be disastrous.

Now the ordinary case which calls for trephining, which I will describe next, cannot admit of any doubt to any one's mind. The patient has received a scalp wound; the same blow has broken the skull. The skull has been driven in, perhaps cracked in several directions. He lies in a state of coma, unconscious, with stertor and all the symptoms of compression. If you can, lift up the bone; if you cannot, you must trephine, and take off all the pressure from the brain. That case, of course, admits of not the slightest doubt at all.

Now comes another case which is not quite so plain. The patient comes in with no scalp wound, has a hæmatoma under the scalp. It is hard to tell whether or not he has a depression, but he has the symptoms of immediate compression. He was struck, fell unconscious, has never roused, remains in a state of coma, with stertor and slow pulse. Such immediate effects produced can hardly fail to be due to depression of bone, because there has not been time for effusion of blood to take place, and this latter brings on the phenomena of compression more gradually.

Given a patient who has received a blow upon the head and has symptoms of compression, it is imperative to interfere. If we find fracture, we should trephine. No one can hesitate with the bone depressed before their eyes and the scalp gaping open, to interfere and remove the piece. It is more difficult to decide and persuade ourselves to cut through the unbroken scalp; to subject the patient to some risk of a wound through the scalp, which he has not already suffered, to relieve symptoms which are somewhat obscure; but if he has distinct symptoms of compression, I think we should not hesitate to interfere to the extent of making thorough incisions, exploring, and acting according to what we find.

In old times one trephined for this. In modern times we should do the same.

Now come more doubtful cases. The most marked of these is where the patient receives a blow, remains conscious some time, becomes gradually unconscious, and we have every reason to believe is suffering from compression from blood inside the skull, a clot. The whole point turns upon whether that clot can be localized; and if it can be localized, whether it can be reached and removed by trephining the skull, and then turning out the clot. The location of the injury, if over a large vessel like the middle meningeal; the slow occurrence of the symptoms; the exactness with which

the symptoms can be defined, must guide us a good deal in this respect; and, it is fair to say, that if we succeed in finding the location of the clot and removing it, and it is outside the membranes, we shall almost inevitably make a brilliant success. The symptoms will be relieved just as they would by taking away a piece of bone; and the patient will recover. If, on the other hand, the blood has been poured out into the arachnoid cavity, we may not find it, and may not succeed in curing the patient. Now it is in this class of cases, which, so to speak, are on the border line between interference and non-interference, that we may apply the principles of modern antiseptic surgery, which renders it so much more safe to trephine than it was formerly. There is no very serious mischief produced by trephining, unless we feel obliged to puncture the dura mater and explore inside the arachnoid cavity, or the brain; then we do subject the patient to a good deal of additional risk; and one must judge for himself, from the appearances of the part beneath, and the non-relief of the symptoms, whether it is wise to persevere. Loss of pulsation in the brain; bulging, etc., all those symptoms must decide us, whether it is best to cut down through the dura mater, and seek for the clot.

Much slower symptoms come on when abscess forms. The patient may have received a slight injury. The symptoms at first may be very obscure, indicating perhaps concussion with contusion; — irritable pulse, and rather sleepless nights; one pupil larger than the other, and a mild form of delirium coming on. This may go on some little time, when suddenly there occurs a chill; usually in the course of five to eight days, sometimes in the second week. After this, a profuse sweat and high temperature; and then commencing symptoms of stupor; growing duller; respirations growing slower; pulse growing slow; other symptoms of compression coming on; until finally, if the patient has no relief, he sinks into a state of profound coma, and dies at the end of a few days. These are the phenomena of suppuration occurring around an injured point in the brain; that is, the brain has been bruised; miliary extravasations have taken place; gradually these have undergone septic changes and have softened; the initial stage of suppuration is marked by the chill; abscess of the cerebrum forms, with all the symptoms of compression added to the symptoms of suppuration. Here is a case, then, where under the old method we should trephine with great hesitancy; under the modern method we are quite justified in trephining; in cutting through the dura mater, and in exploring, in the hope of finding pus and letting it out. If we fail, the patient certainly is not any worse than before. He was truly on the road to death under the symptoms he had before. If we succeed, and evacuate the pus, and drain and wash out the cavity, occasionally we get a cure.

These responsibilities are very serious, and we want to be quite clear that the diagnosis is fairly certain, that the patient is quite sure to die as he is going on, before we venture on so profound an injury to the brain, in the hope of finding a suppurating centre. Hence we see that certain cases are quite clear; while some are quite doubtful. We are encouraged to trephine much oftener than formerly on account of the immunity afforded by aseptic surgery.

There is a class of cases where in old times no one would have thought of interfering, and in modern times people do interfere, and which may be classified as cases where the operation may be justifiable, or may not be justifiable, according to the light of statistics. Such cases as these are essentially chronic cases; cannot be acute ones. Acute ones drive us to a decision, one way or the other, at once. The phenomena are so severe that they usually are pretty clear; but it is the chronic case that can be considered for days; and whose whole history is to be gone over for months; the family history to be considered; whether the patient has descended from epileptic parents; or whether he possibly has original, or inherited syphilis; all these things have to be weighed thoroughly, before we trephine these chronic cases. We trephine, nowadays, for epilepsy; for scar-tissue thought to be the seat of chronic headache and to produce epilepsy; for syphilitic thickening; for syphilitic gummatous tumor; for brain tumors of another class which are usually either soft glioma or sarcoma; and for tension, meaning by that something inside the head which is pressing the brain; irritating; and which may be relieved by cutting a hole in the skull; then cutting open the dura mater, and allowing the tension to be taken off; the serum to drain away; and more room to be given to the parts. For all these things, trephining is occasionally done. It is frequently done without any relief to the patient. It is fair to say, it is frequently done without any damage to the patient. It is extraordinary how under modern antiseptic methods, a good many of these doubtful cases are explored and then heal up; and, apparently, are neither better nor worse than before. Some of them occasionally get better.

There is a curious affection of the brain, after the membranes have been cut away, which used to be called hernia of the brain. The pulsation of the brain inside the head, apparently, the moment the tension of the enveloping sheath of the membrane is taken off, pushes the soft brain substance up into the opening; tends to protrude it more and more; and gives rise to a species of tumor, which used to be called hernia of the brain. It has been proved, I think, that the mass that grows out in these openings is not really so much brain tissue, as a sort of irregular fungus growth; a proliferation, which takes place on the surface of the brain. It is difficult to treat. It is frequently fatal. In the older times of surgery it was very commonly fatal, and was very much dreaded. Compression, if applied too forcibly to restrain its pushing out, may produce symptoms of coma and compression of the true brain beneath. Agents applied to it in the shape of styptics, or astringents, or escharotics have to be used, of course, with a great deal of caution, because that also may light up a meningitis; or destroy true brain-tissue and lead to cerebral abscess. Under the modern treatment hernia of the brain seems to get along much better than it used to; and it is quite encouraging that it does. Keeping it packed antiseptically with gauze; keeping up moderate pressure, seems to check the fungus proliferation and the formation of serum and pus, which formerly took place to a great degree; and some of these forms of hernia can be led to heal without serious symptoms.

To sum up briefly: We must never forget that any head injury may become serious; that even a slight concussion is not safe, until a fortnight has elapsed; that it is more dangerous in the child than in the adult; that the child who has received a concussion is certainly not to be considered safe, until two weeks have elapsed, although the first few days of headache may have passed off; that this is especially true, and to be

regarded with great care and suspicion, if the child happens to inherit a tuberculous constitution, because tubercular meningitis is very easily provoked in such a child; that all head injuries, which are at all severe, are well treated by the old antiphlogistic method, aided by antisepsis (by this I mean reducing and quieting treatment, in various forms); that antiseptics have given us greatly increased advantages in treating scalp wounds, fractures of the skull, inflammations of the brain, extravasations into the brain, and tumors in the brain, from whatever cause; that there are certain very simple rules to be followed with regard to trephining — a few cases which are plain and apparent, such as direct, compressing fractures which are compound; fractures which are not compound, but still are compressing; and punctured fractures; that there is another class of cases where we trephine for clot, or abscess, where the diagnosis is a little more difficult, but still where there is a fair percentage of success; and, finally, there is a very large class of chronic cases, where we balance the probabilities, where we are encouraged occasionally to interfere by trephining, and encouraged especially by the fact that trephining is not the fatal operation that it used to be.

THE MISUSE OF DRUGS IN MODERN PRACTICE.[1]

BY JOHN T. G. NICHOLS, M.D., OF CAMBRIDGE.

Mr. President and Fellows of the Massachusetts Medical Society: — The first article in the Code of Ethics adopted by this Society declares that "a physician should lend his influence to encourage sound medical education, and to uphold in the community correct views of the powers and limitations of medical science and art."

This Society has always held that education is the only source of a sound practice of the medical art. While it has fairly stated the powers of the art, it has not failed to speak of its limitations in plain and honest words.

Much as the Society has done in the past, the work is not finished. The war against ignorance and superstition is a never-ending one. This community guards its property with jealous care. The lawyer cannot practise his profession until he has passed the examination of the court. The pilot, who brings the merchandise of our citizens safely into port, must have proved his ability before the proper tribunal. Even the drain-layer must have a license, and presumably have shown his fitness for his work.

Not so does it deal with those who profess to cure the diseases of its people. The educated physician and the quack stand on equal terms before the law. Other States have passed laws which have driven out ignorant pretenders to medical skill. We have opened our doors to them. They have become so many and so strong as to prevent the enactment of a law to compel every one who claims to be a practitioner of the art of healing disease to prove his knowledge of its fundamental principles. What a comment on the good sense of our community in the closing years of the nineteenth century. The man who lays a drain must have a license; the man who deals with the health and lives of its people needs none!

[1] The Annual Discourse delivered before the Massachusetts Medical Society, June 14, 1893.

The only explanation of such a want of common sense in a community so intelligent as ours, is that incorrect views of the powers and limitations of the medical art still prevail. Disease is still looked upon as the result of some malign force. Drugs are still thought to be the most efficient agents to cure it. The advertising pages of the newspapers are filled with promises of cure for all the "thousand natural shocks that flesh is heir to." The mails are flooded with circulars, the streets littered with hand-bills, relating wonderful cures of diseases which have baffled the skill of regular physicians. Money is freely expended in this business by men who look for a return from their investments. That it is a profitable enterprise is shown by its growth. While it is not new, it was never so extensive or so elaborate in its methods as now. Our patients, when they carry our prescriptions to the apothecary, see large stocks of these proprietary and secret remedies on his shelves. The great stores, where almost everything is sold, advertise "cut prices" on these goods. Grocers, even, display them by the side of articles much more tempting to the taste. How largely they are used this audience well knows.

The grosser forms of quackery which claim supernatural powers, finding their victims among the superstitious, who are not always ignorant people, I need not describe. This Society is not responsible for them, nor for the folly of those who resort to them. But when we consider the widespread belief in the community, that drugs are always useful, and generally necessary in the treatment of disease, we may well ask if we are not, in some degree, responsible for it.

Each generation is prone to think itself wiser than those that have gone before it. We admit the mistaken practice of our forefathers. We congratulate ourselves that the day of blood-letting, of mercurials, of disturbing medicines in general, has gone by. We see that faith in drugs, still so prevalent, was the lesson taught by the profession in those earlier days. Do the modern methods of treating disease justify the public in maintaining this belief?

I ask you to listen to some considerations upon the misuse of drugs at the present time; the limitations to their usefulness; and the powers of the medical art which have been gained from other sources than drugs.

It is often said that we do not give as much medicine as our fathers did. If this is true, it is not due to a want of material. We are told that Hippocrates mentions only two-hundred and sixty-five drugs in his writings.[2] The Pharmacopœia of this Society, published in 1808, includes the materia medica and its preparations and compositions in one hundred and seventy duodecimo pages. If we compare this book with the last revision of the United States Pharmacopœia, or with the last edition of the United States Dispensatory, we may well doubt the truth of the statement.

It is true that the Dispensatory includes many obsolete and inert drugs, but the list of medicines in daily use is many times longer than that of our early Pharmacopœia. Nor is it yet completed. The mineral, vegetable, and even the animal kingdoms are almost daily giving us new remedies. The chemist, by skilful synthesis, makes new compounds out of old ones. The pharmaceutist combines and offers in attractive and convenient forms the many drugs which the modern system of treatment demands.

[2] Encyclopædia Britannica: Art. Medicine.

Our drugs have gained in power as well as in number. A large part of the old Pharmacopœia of our Society consisted of drugs of little power for harm. To produce any effect, the doses were so large, and so repulsive to sight, smell and taste, that the fortunate power of the stomach to reverse its muscular action often saved the patient from harm. Now the chemist has separated the active principles of drugs, giving us agents of great power for harm, as well as for good, in doses so small as to be easily taken. The art of the pharmaceutist has made them inoffensive to the taste. Copying the wisdom of the serpent, we inject them under the skin, beyond the power of a perhaps outraged nature to reject them. The minuteness of the medicinal dose of some of these active principles would have been called almost infinitesimal by the physician of fifty years ago. There can be no question that both in the number and potency of our drugs, we are far in advance of our fathers. So far, we justify the views of the community as to the importance of drugs.

In Article V of our Code of Ethics we read: "But a physician should lend his influence to establish a distinct line between the regular practice of medicine and the practice of quackery, and should avoid any act which might tend to weaken such a distinction either in the professional or in the public mind."

Do we observe this rule, or do we tolerate or even sanction methods of using drugs which violate it?

Until within a few years, new drugs were brought to our notice through regular channels. We read of them in reputable journals. Men, whose names gave weight to their opinions, recorded their experience of them. They were discussed in medical societies, and their power for harm as well as for good was fully and fairly stated. Pharmaceutists of good repute prepared them, and briefly advertised their readiness to supply them. The advancement of medical science, the improvement of the medical art, were paramount considerations. The distinction between the ways of regular medicine and quackery was so sharply defined that no one could mistake them.

In these days, new customs have arisen. The pharmaceutist no longer contents himself with providing the profession with the drugs which its experience approves. He aims to direct the medical art. He proclaims the virtues of new drugs, ignoring their dangers. He vaunts the superior qualities of his own wares. Imitating the business methods of his quack rivals, he scatters his circulars broadcast among the profession, containing promises of cure and certificates of results which would do credit to the advertising agents of the rival Sarsaparillas. Let me read a specimen of the therapeutic literature which they so freely bestow upon us;

"When Papoid is applied to the diphtheritic membrane, four distinct though allied effects are observed. That it seems to have a penetrating property which is exerted with such rapidity that when once really applied no amount of washing of the parts will remove it.

"That in a few hours the membranes are dissolved or detached, and do not re-form, because

"The bacteria of the disease are also destroyed.

"The formation of the specific poison or 'toxalbumen' of diphtheria is arrested, and abnormal bodily temperature falls.

"The removal of the morbid growths from the throat relieves at once the embarrassment of respiration, and in a large majority of cases a complete cure is effected."

Many other useful properties of this medicine are set forth. The inferiority of pepsin is asserted. Not to be outdone by the quack, the case of a "blind ischio-rectal fistula of twenty years' standing" is related:

"This case had been operated upon repeatedly, and treated by some of the best men in the country. All treatment had failed. I had operated upon and treated the case for about a year, and had given it up as one beyond my ability to manage. What I am about to state may seem somewhat startling, but it is none the less true. After proper preparation of the fistulous tract, one injection of Papoid effected a cure."

Here the writer's conscience seems to have pricked him, for he adds, "At least it has been well for about two months." [3]

Having, by such means, brought us into a state of "expectant attention," he follows up his communications by a personal interview. His agents, men who have some knowledge of medicine if he can get them, enter our offices with the assurance of "drummers" in a country grocery. We are treated to long lectures on therapeutics if we will listen to them. Samples are spread upon our tables until our rooms look like the commercial travellers' apartment in a hotel. We are told of the good results their remedies will secure; that we cannot afford to be without them; that our neighbors have ordered a supply; and that, if we do not wish to be behind the times, we must also give them an order.

Leaving a sample for trial, a two-ounce bottle of cod-liver-oil emulsion, perhaps, they depart, to be followed in quick succession by their rivals, who extol the virtues of their own preparations, and point out the defects of those of their predecessors.

There is one striking feature both of their literature and their lectures. Their medicines are always successful. A few days ago, I called the attention of the agent of one of the oldest firms in the country to this fact. "We have no use for unsuccessful cases," was his frank reply.

Not satisfied with copying the methods of the quack, they imitate those of the educated physician. So-called medical journals, marked sample copies, come to us with the regularity of those we pay for. They contain a few articles of merit, copied from some regular journal, but consist almost entirely of advertisements and testimonials recommending the medicines of some manufacturing firm, "A splendid remedy," "A grand combination," "I would not be without it for any consideration," "Send me a dozen bottles." Who does not know this yellow-covered literature of modern medicine?

But these enterprising business men do not stop here. Their money buys the advertising pages of some of our best journals. Let me read some specimens of their art:

"PONCA COMPOUND. Uterine alterative. Exercises a specific alterative action on the uterine tissues, a general tonic influence on the pelvic organs; has a tendency to absorb plastic deposits, to regulate the vascular supply, to relieve congestion, to tone up the nerve forces, to encourage persistalsis of the bowels, and to remove spasmodic conditions. 100 tablets mailed on receipt of $1.00."

"FEBRICIDE, the only complete antipyretic of the materia medica. It sustains the patient, it reduces the temperature, it kills the fever. A restorative of the highest order. A powerful anodyne. Invaluable in malarial dis-

[3] Papoid Digestion, etc. Johnson & Johnson, manufacturing chemists, 92 William Street, New York.

eases. A positive remedy for rheumatism and neuralgia. A specific for *la grippe* and pneumonia. The national antipyretic."

"Dr. Borst's PYROLIGNINE, the new 'wood tar' product. Antipyretic, anodyne, nervine. Reduces temperature. Subdues pain. Restores nerve power. No secondary effects. A remedy of pronounced value in acute inflammatory fevers . . . and all affections in which fever, pain and restlessness, alone or combined, are to be governed."

"LIQUEUR DE LAVILLE. A prompt, tried and infallible specific for gout in all periods of the attack. Dose, one to three teaspoonfuls daily. Professor Brown-Séquard, at a meeting of the Paris Society of Biology, October 15, 1887, said: 'Laville's well-known remedy acts marvellously well in gout, in witness of which I cite the following circumstance which occurred under my own observation. Dr. Fleury, of the French Faculty, and also author of several works on hydrotherapy, had an attack of complete paralysis of the right side, with anæsthesia and aphasia. Precursory symptoms having appeared on the night before, he directed that in case he would be unable to read or write, a large dose of Liqueur de Laville should be given to him, provided I saw no objection to it. I assented. Two hours afterward, all symptoms of paralysis had disappeared."

Thinking it worth while to investigate this remarkable preparation, I wrote to the firm advertising it, for its formula. The answer was as follows: "We are sorry to say we cannot give you the formula of 'Laville's Liquor' exactly; have been informed that it contains colchicum and colocynth; from practical experience we know it to be a very useful remedy for Gout and Rheumatism."

"WHEELER'S TISSUE PHOSPHATES. . . . As reliable in dyspepsia as Quinine in ague. . . . It renders success possible in treating chronic diseases of women and children, who take it with pleasure for prolonged periods, — a factor essential to maintain the goodwill of the patient. Being a tissue constructive, it is the best general utility compound for tonic restorative purposes we have; no mischievous effects resulting from exhibiting it in any possible morbid condition of the system."

"'To lessen the fever and strengthen the heart is the first duty.' — *Fothergill.* FEBRINA TABLETS lessen the fever gradually with absolute safety. CACTINA PELLETS strengthen the heart safely with absolute certainty."

These quotations are not taken from the Sunday newspapers, as you might infer, for nothing in those papers exceeds them in impudent claims to marvellous powers. They are copied from the advertising pages of a single issue of the *Boston Medical and Surgical Journal.*[4]

Made bold by success in this field, one firm has thrown off the mask, and asserts its claim to lead in the art of medicine. In an advertisement in the same journal, we read:

"In medical practice there are many 'hard questions' arising daily. The busy practitioner is settled in his own mind. Frequently, however, he has not analyzed the reasons leading to his conclusions. *Merck's Bulletin* does the thinking, the analyzing, the proving. It gives him a reason for the faith that is in him. It covers the entire field. . . ."[5]

It is not so strange as it appears that our community does not discriminate more carefully between the educated physician and the charlatan. Such material as I have brought to your notice may be, and doubtless is, used with good effect by the quack. Laid before a committee of our legislature, when a bill to regulate the practice of medicine is before it, I cannot wonder that the report is, "inexpedient to legislate." By tolerating such methods we endorse them, and thus violate both articles of our Code of Ethics, from which I have quoted.

As to the conduct of our medical journals we have the remedy in our own hands. It may be that the editors cannot control the advertising pages. It may be that the publishers would lose money, if such advertisements should be excluded. The subscribers can make an effective protest, if they choose to do so.

Let me not be understood as condemning all advertisements of drugs, or all communications of the pharmaceutist to the physician. There are some firms whose publications are always welcome, because they are not inspired solely by the desire for gain. But there can be no question as to the evil effects of such methods as I have named.

According to Hippocrates, the medical art began with the discovery that food which is good in health is hurtful in disease: "For the art of medicine would not have been invented at first, nor would it have been made a subject of investigation (for there would have been no need of it), if, when men are indisposed, the same food and articles of regimen which they eat and drink when in good health, were proper for them, and if no others were preferable to them."[6]

Observation and experience soon led to the use of drugs. But then, as in the day of Hippocrates, and at the present time, "experience is fallacious, and judgment difficult." The great master dispelled the clouds of ignorance and superstition which had so long hindered its progress, and placed the art of medicine on the secure foundation of accurate observation and sound deduction. He recognized the healing power of nature as the corner-stone of our art. He taught the self-limited nature of many diseases. The crude humor became concocted in due season, and at fixed periods was expelled by various channels. While drugs were of use at certain stages, the critical discharge could not be interfered with safely. To remove the cause of the ailment, to put the sick man under the most favoring conditions for recovery, were the essentials of his practice of the medical art. Drugs held a subordinate place. In his reports of cases, which would serve as models for the medical writer of to-day, hardly any mention is made of treatment. Had the successors of this great man followed in his footsteps, the art of medicine would be as near perfection as our knowledge would allow.

But the inductive method was too slow in its movements. Theory soon gave birth to systems of medicine, which, ignoring or undervaluing the power of nature to heal disease, asserted the curative action of drugs. One theory flourished, soon to be overthrown by another, differing from it only in the kind of drugs, or the mode of using them. At intervals a man appeared who tried to lead his fellows into the ways of rational medicine. Sydenham revived the inductive methods of Hippocrates, and impressed upon his age the doctrine of the vis medicatrix naturæ, and the duty of the physician to follow its teachings. Again, systems, the offspring of theory, pass in quick succession across the stage of history. One of these, fantastic in its conception, exceeding all others in its reliance upon drugs, survives and flourishes at the present day. Always having its strongest supporters among the educated

[4] August 11, 1892.

[6] The Genuine Works of Hippocrates (Sydenham Society), vol. i, p. 162.

classes, its success was, and is, a protest against the use of powerful drugs in effective doses, in the present state of medical science. However strongly its patrons may declare their belief in the efficacy of its infinitesimal doses, their common-sense teaches them that the tenth attenuation of nux is safer than the thirtieth of a grain of strychnia.

The discourse of Jacob Bigelow, read to this Society nearly sixty years ago, and the work of Sir John Forbes on "Nature and Art in Disease," marked a fresh revival of rational medicine. This Society took a prominent part in this movement. From this platform have come protests against the abuse of drugs which have an application to the present day.

For many years after this revival, the rational method of treating disease was the prevailing one in this community. As defined by Bigelow, whose discourse above mentioned did so much to establish it, it "recognizes nature as the great agent in the cure of diseases, and employs art as an auxiliary, to be resorted to when useful or necessary, and avoided when prejudicial."[7] Once more more our art was brought back to the path marked out by its founder.

(To be continued.)

FORCIBLE CORRECTION OF ANGULAR DEFORMITIES OF THE KNEE, WITH A REPORT OF CASES.[1]

BY JOEL E. GOLDTHWAIT, M.D., BOSTON.

In any inflammation about the knee-joint, in which there is muscular irritation, the leg flexes; and if this condition be kept up for any length of time, the head of the tibia is drawn backwards, so that the normal relations of the articular surfaces are lost. The knee is flexed and the tibia subluxated backwards.

The cause of this double deformity lies in the direct insertion of the posterior thigh muscles, and in the method of application of the power of the Quadriceps group.

At times rotation of the foot and leg outwards is seen in connection with these other deformities. This is probably due to the fact that the Biceps tendon is inserted far out upon the head of the fibula, and consequently has a longer lever upon which to act than the inner Ham-string group, which antagonizes the Biceps in rotating the leg.

The treatment of these deformities by means of force suddenly applied is not new; nevertheless, from a limited experience, I am confident that the method has received too little attention, and that patients are allowed to go without operation and to remain cripples, or else more serious operations are performed than is necessary. This lethargy undoubtedly is due partly to an incomplete understanding of the operation, but still more because of the faulty apparatus for such use which we have had at our command.

It is with the hope that by a free discussion here to-night we may arrive at a better understanding of the subject, that I present this paper, and offer the deductions which I have made.

[1] Read before the Orthopædic Section of the New York Academy of Medicine in New York, May 19, 1893.

[7] Brief Expositions of Rational Medicine, by Jacob Bigelow, M.D., Boston, 1858, p. 27.

Clinically, as these cases are seen, they group themselves pretty definitely into three classes:

(*a*) Those that are seen during the acute or subacute stages of the disease, in which the deformity is maintained entirely by muscular spasm.

(*b*) Those in which there is complete bony anchylosis, as the result of extensive osteo-arthritis.

(*c*) Those in which the malposition is maintained by adhesions in or about the joint, as the result of old arthritic or peri-arthritic disease.

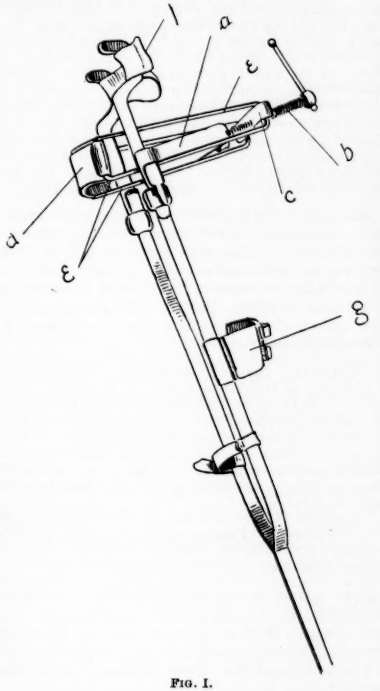

FIG. I.

The first two classes are dismissed entirely, as forcible straightening should not be considered in their treatment. In the first class simple continued extension, with complete immobilization of the joint, will be found to be all that is necessary; while, in the second class, some bone operation, such as excision or osteotomy, will be required. Forcible correction of the deformity in either of these groups would do harm. In the first, the acute trouble would be increased, while in the latter, fracture of the bones, with laceration of some of the soft structures would result.

The third class, which really represents the intermediate position between the other two, includes all of those cases in which the malposition is maintained by fibrous adhesions, without regard to the original disease, whether tubercular or otherwise. If the adhesions be slight, they can be broken up with the hands, and the deformity corrected; but if, as is usually the case, the adhesions be firm, the correction is a

very different matter, and mechanical appliances become necessary.

In a paper which was printed in the Boston *Medical and Surgical Journal* of December last, I described

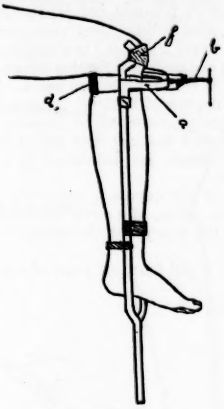

Fig. II.

an apparatus (Figs. I and II) for use in the correction of such deformities. It is a modification of an apparatus, devised several years before, by Dr. E. H. Bradford; the modifications being made to make the apparatus adjustable, to make the application of the after this the apparatus is applied, with the leg flexed. The posterior band, *d*, is then screwed forward; and after as much force has been applied as seems prudent, the leg is straightened as much as possible, by means of the long lever handle, the power being applied intermittently. The apparatus is then taken off and the leg again manipulated with the hands, to still farther break up the adhesions; after which, with the apparatus, the complete correction is attempted. In a mild case one application may be all that is required, while in others several applications (at one sitting) may be necessary before the position is entirely satisfactory.

At times, when the apparatus is finally removed, the head of the tibia drops back and cannot be held in place, even though the leg be straight, because of the firm contraction of the Ham-string tendons. This may be overcome by division of the tendons, or what was better in one of the cases, the leg was put up slightly flexed, enough to relax the contracted parts, and the dressings allowed to go undisturbed for one week. At the end of that time the tendons had relaxed so much that the leg could easily be straightened, and the correct apposition of the bones maintained. During the operation, the rotation of the leg, which is due to one condyle of the tibia slipping farther back than the other, can be corrected very easily, by simply rotating the apparatus so as to bring the greatest pressure upon the condyle that is posterior. If this last deformity be allowed to remain, it not only produces an awkward gait, from the turning out of the foot, but also, from the posterior position of the outer condyle of the tibia, a more or less marked knock-knee is produced.

Fig. III.

Fig. IV.

Fig. V.

power more easy and more under control, and to have the counter-pressure so directed that no damage could be done to the femur. Its mechanical principles are simple, and its adjustment and use is not difficult.

The operation, which is always performed with the patient anæsthetized, may be briefly described as follows: First, the adhesions are broken up as much as possible with the hands only (this in some cases means a good deal, and in others practically nothing); and

At times, however, the knock-knee is due to an elongation of one condyle, as a result of the disease, and a Macewen osteotomy may be necessary; but it is best to wait a few weeks, at least, as in one of the cases in which this deformity was well marked, it entirely disappeared without operation, evidently being due to an old inflammatory deposit on the inner side, which was absorbed.

The after-treatment is simple. A plaster-of-Paris

bandage is applied at the time of the operation, and is not disturbed for one or two weeks; after which the patient is allowed to go about upon crutches, the knee being fixed with the plaster bandage, or, what is better, with a Thomas knee-splint. In a few weeks the apparatus is omitted at night, thus favoring the establishment of motion in the joint; but while the patient is up and about, the splint or some protective appliance should be worn, for from six months to a year.

The pain, which is surprisingly slight, can usually be controlled by the salicylates. Morphia, of course, is to be used if necessary.

FIG. VI.

FIG. VII.

FIG. VIII.

The following four cases have been operated upon since the paper of last December was published; and in each case the apparatus, figured above, was used.

CASE I. A young woman, sixteen years of age. When thirteen months old, the right leg "drew up," and it has remained in that position ever since.

Figure III represents the position of the leg at the time of entrance to the Massachusetts General Hospital, in December, 1892, flexed to a right angle, with marked subluxation of the tibia, and with only a few degrees of motion in the joint. There was considerable cicatricial tissue in the Popliteal space, but little or no bony thickening.

She was operated upon, and the position corrected without much difficulty. In ten days she was up in a wheel-chair, and was about on crutches a week or two later wearing a caliper splint.

Her condition at the present time, six months later, is best understood from the accompanying cuts (Figs. IV and V), which represent the leg straight, and also flexed to show the amount of voluntary motion that it is possible; almost ninety degrees.

CASE II. A boy eight years of age. Six weeks before being seen at the Boston City Hospital, in December last, the patient received a wound of the knee-joint, in which the patella tendon was divided. The wound had been neglected, and as a result of the suppuration which followed, the joint structures were badly disorganized. When first seen, the tibia had slipped back, as the result of the absence of the anterior ligaments and tendon, so far that there was scarcely any articulation between the two bones. There was about twenty degrees of flexion. After waiting some time for his general condition to improve, the operation was performed and the tibia drawn forward into place. The position was maintained by a plaster-of-Paris bandage.

The result in this case is a useful leg, but with a stiff knee-joint. This, of course, was expected from the nature of the injury and the subsequent suppuration.

CASE III. A girl fourteen years of age. In January of this year the patient entered the Massachusetts General Hospital, with the leg flexed about forty-five degrees (Fig. VI); the deformity having existed for twelve years. There were several degrees of flexion possible, but extension was restricted, as is shown above, and this limitation of motion was evidently due largely to the position of the patella, which was firmly adherent to the femur.

With the correcting appliance the leg was straightened without difficulty; and as the force was applied, the adhesions between the patella and the femur gave way, allowing free motion between these bones.

The patient was up in a chair the second day after the operation, and a few days later was about on crutches.

At present, about six months later, the leg is straight, as is shown in Fig. VII, and voluntary motion is possible to the position shown in Fig. VIII.

CASE IV. A woman twenty-one years of age. In December of last year the patient entered the Boston City Hospital, and gave the following history. Eleven years previous, she fell striking the right knee. This

was followed by an abscess which opened just below the patella, and from which there has been a slight discharge ever since. At the time of the appearance of the abscess the leg "drew up," and has remained in that position until now. At the time of entrance to the hospital, it was flexed to about a right angle, and subluxated as is shown in Fig. IX. There were only a very few degrees of motion possible.

On December 21st, Dr. Bradford opened the sinus

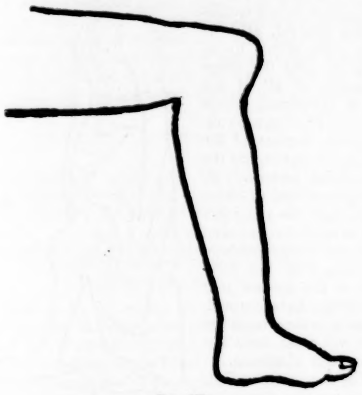

Fig. IX.

below the patella, and removed with a curette, a large amount of dead bone from the head of the tibia. The cavity remaining was about the size of a small lemon. At this time, the correcting apparatus was applied, and the leg partially straightened; but because of the danger of fracturing the tibia in its weakened condition, the correction was not completed.

Two months later the cavity in the tibia having filled up, the apparatus was again applied and the leg fully straightened.

At the present time the patient is walking about, wearing a Thomas caliper-splint, with the leg straight, as is shown in Fig. X, and with several degrees of voluntary motion (Fig. XI). The pain which had been constant before the operation has entirely disappeared.

I am indebted to Dr. C. B. Porter for permission to see Cases I and III, to Dr. M. F. Gavin for Case II, and to Dr. E. H. Bradford for Case IV.

Fig. X.

Fig. XI.

I wish, also, at this time, to give a later report of one of the cases of the December series. The patient was a girl sixteen years of age, in which the deformity had existed for eight years before the operation. It is now a year since the leg was straightened, and all apparatus has been omitted for about two months. She walks well, there being enough motion in the joint to prevent the marked limp common with a stiff knee, and there are no uncomfortable symptoms. Fig. XII shows her condition before operation, Fig. XIII, the leg straight, and Fig. XIV the amount of voluntary free motion.

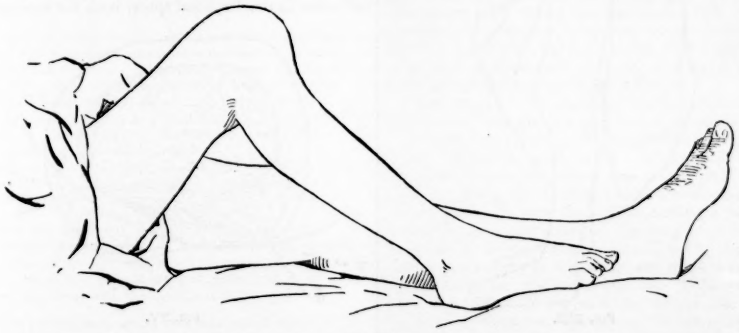

Fig. XII.

In considering these cases, Case I seems to be worthy of special attention, and is of interest as a

physiological experiment as well as a surgical result. The fact that a joint can be put out of use for nearly fifteen years, and then restored to use with very nearly the normal amount of motion, is not only a matter of interest but of surprise. To be sure, the original disease had been largely in the tissues about the joint, judging from the position of the cicatrices; but even where there has been no joint injury or disease, as in fractures of the long bones — in which it is necessary to confine the adjacent joint for a long time — it has always been supposed (except for Dr. Phelps's experiments on dogs) that the functions of the joint would be seriously impaired, due to the formation of fibrous adhesions inside of the capsule. In this case, in one week from the time of the operation there was nearly normal voluntary motion without pain; at least strongly suggesting that no intra-articular changes had taken place.

FIG. XIII.

The results in the other cases need no special comment; the illustrations represent their condition better than any verbal account.

In calling attention to this treatment it is to be understood that the original cause of the deformity is of little consequence, and that whether it be rheumatic, gonorrhœal, or tubercular; or whether the disease has been confined to the joint or to the structures about the joint, the deformity can be corrected as thoroughly and without much more danger, in one case as in the other. In the tubercular cases a considerable interval, at least two years, should be allowed after the disappearance of all of the acute symptoms, before the correction be attempted, because of the danger of starting up the tubercular process. In the gonorrhœal or rheumatic cases the apparatus can be applied at any time where it is reasonable to suppose, from the duration of the disease, that adhesions have formed. Usually in these cases the pain will cease with the restoration of motion.

FIG. XIV.

The dangers attending the use of the apparatus are very slight, if its principles are understood and ordinary precautions are used.

In the acute cases, and in those in which there is bony anchylosis, its use is contra-indicated, for reasons stated above. The danger of lacerating the vessels and nerve in the Popliteal space, from the application of so much force, is very slight. As was shown in the paper before referred to, the head of the fibula, and the inner condyle of the tibia act as buttresses; and upon these points the pressure is applied, while the vessels lie deep in the muscles entirely protected, as is shown in Fig. XV. In cases of extensive peri-articular disease behind the joint, it would be better to straighten the leg gradually, gaining a little with each operation, rather than to correct it at one sitting; in which case the vessels might be lacerated, from being involved in the old cicatrix. This precaution should

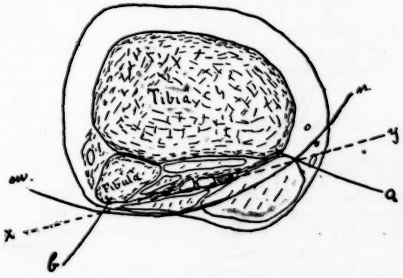

FIG. XV.

also be taken in elderly persons in which atheromatous changes in the vessels are to be considered.

CONCLUSIONS.

A special apparatus is presented for the correction of the angular deformities of the knee in which there is fibrous anchylosis. Five cases are reported in all, of which the ultimate results, as to usefulness of the leg, are very good. One case, in which the deformity had existed almost fifteen years, has nearly normal motion in the joint. One case is reported in which all apparatus has been omitted one year after operation. In none of the cases has any acute trouble resulted. The operation and the use of the apparatus is not difficult, and the dangers attending its use are comparatively slight.

SUBPHRENIC ABSCESS, WITH SPECIAL REFERENCE TO THOSE CASES WHICH SIMULATE PYO-PNEUMOTHORAX.[1]

BY A. LAWRENCE MASON, M.D.,
Associate Professor of Clinical Medicine in Harvard University; Visiting Physician, Boston City Hospital.

(Concluded from No. 9, page 220.)

This is by no means an exhaustive review of the subject, but there are few individual records of more than one or two cases, and I will refer to some of the more interesting ones as briefly as possible. Bristowe[53] reported two cases in an article on "Abscesses in the Upper Part of the Abdomen"; and more recently Dickinson and Ewart,[54] of St. George's Hospital, have recorded "two cases of perforating ulcer of the stomach with misleading physical signs," one of which, entitled "Perforation, with Supposed Pneumothorax," is similar to others which have been quoted. But the second, "Perforation, with Supposed Pericarditis," deserves attention.

Case. — A chlorotic girl, aged twenty-four years, was admitted with symptoms which were considered those of perforating gastric ulcer. There was pleural friction in the left axilla, and over the præcordia were tenderness and friction sounds which had all the characteristics of those heard in pericarditis. Syncopal attacks. These signs appeared to indicate that in addition to peritonitis and pleurisy there was also pericarditis.

Autopsy: Perforation of the posterior wall of the stomach, with peritonitis, which was almost restricted to the left half of the diaphragm and the upper surface of the left lobe of the liver. The abscess pushed up the left side of the diaphragm, which showed pleurisy on its upper surface. Soft lymph coated the lower parts of the left pleural membrane. *No pericarditis.* The roughened pleural surfaces, diaphragmatic, costal, and pulmonary, had given rise to a friction rub synchronous with the heart's action.

This pleuro-pericardial rub was noted in the original case of Wilks and Barlow, and the mode of causation was then also observed. It also occurs in pneumonia, with pleurisy of the left side, and Flint states that in character this sound cannot be distinguished from the true pericardial friction. But the graver symptoms of pericarditis are casually wanting.

Case. — An interesting case is that of Schenck.[55] A woman was operated on for subphrenic abscess by resection of the eighth rib. Pneumothorax was caused thereby, and the upper surface of the diaphragm was united to the parietes before incision of the abscess to keep the pus out of the pleural cavity. The patient died, however, of sepsis, and at the autopsy transposition of the viscera was found.

Flint, in his *Practice of Medicine*, refers to the observations of Leyden and gives his conclusions, but does not mention having met with similar cases in his own experience.

Gee[56] says: "An abscess below the diaphragm may become partly filled with air and may so raise the diaphragm as to give a tympanitic percussion note over the lower part of the chest, but not the amphoric signs of pneumothorax."

This is evidently an error, which was pointed out by Coupland in the *British Medical Journal*, March 23, 1889, where he reports a case of subphrenic abscess of the right side, with signs of pneumothorax, probably caused by perforation of the vermiform appendix and cured by operation.

As the editor of the posthumous work of the late Dr. Wilson Fox,[57] on *Diseases of the Lungs and Pleura*, Coupland has appended a concise description of the condition now under consideration, reproducing Leyden's plate.

Strümpell[58] had repeatedly seen perforation into the left pleural cavity from gastric ulcer, with septic pleurisy and sometimes pulmonary gangrene. Therefore, he says: "Whenever we meet a case of apparently spontaneous, left-sided empyema, we should at any rate always think of the possibility of gastric ulcer."

In Pepper's *System of Medicine*,[59] in the article by Welch, on "Simple Ulcer of the Stomach," attention is called very clearly to the etiology of the class of cases under discussion, and the conclusions of Barlow and Leyden are quoted. The author also mentions Pfuhl's experiment with the manometer in Leyden's clinic, which goes to show that the pressure in the abscess cavity rises during inspiration and falls during expiration, the reverse being true in the pleural sac. But it is stated that Schreiber[60] has shown that this point does not hold good when the diaphragm moves little, as is often the case in this affection.

Osler[61] says: "The condition of pyo-pneumothorax subphrenicus may simulate closely true pneumothorax."

Vierordt,[62] in speaking of "Subphrenic peritonitis," says: "We understand by this an ichoro-purulent, sacculated peritonitis below the diaphragm. From paralysis, partly also from irritation, the diaphragm is pushed very high into the thorax, causing a marked retraction or compression of the lung of that side. That half of the thorax is broadened, and by the presence of pus and gas in the cavity, one is apt to mistake the condition for pyo-pneumothorax. Peritonitis of this character usually begins at the stomach, as an ulcer, or at the intestine, especially at the vermiform appendix or cæcum. In making a differential diagnosis, we observe whether, in the *status præsens* or in the previous development, there were indications of disease of the lungs, or, on the other hand, of the abdomen; and also whether the lung of the diseased side still performs the motions of respiration."

DIAGNOSIS.

The diagnostic points in these varied conditions have, perhaps, been sufficiently indicated by the foregoing citations and cases, but it seems to me that enough stress has not been laid upon the incompleteness and inconstancy of the signs in "false pneumothorax" as compared with the true, or upon their peculiar localization both above and below the usual position of the diaphragm. The metallic sounds may be loudest at the epigastrium. The adhesion of the lung to the diaphragm and parietes is an important indication of the inflammation below, as is the dry pleurisy which precedes this adhesion. A serous or purulent effusion in the back is misleading, but the patients always appear to be in much worse condition than a simple pleurisy would cause. Diaphragmatic hernia may present similar physical signs, but the history, usually of traumatism, is different.

PROGNOSIS AND TREATMENT.

The prognosis depends almost entirely upon the efficacy of surgical treatment by free incision and drainage, although cases of spontaneous evacuation and cure are not unknown. Tillmanns,[63] of Leipzig, in his article relating to the operative treatment of abscesses resulting from communication between the gastro-enteric tract and the thorax, reports a successful case of thoracotomy in a boy, fifteen years old, in whom a supposed intestinal perforation had caused an abscess which found its way through the diaphragm. Feculent-smelling fluid, which contained food, was evacuated from the right pleural cavity and recovery ensued. Tillmanns, after an elaborate discussion of twenty-two cases, expresses the opinion that the cure of subphrenic abscess may be effected by antiseptic drainage when the suppuration is not too extensive, if it remains shut off from the peritoneal cavity, and if the intestinal or stomach perforation heals spontaneously.

That the gastric ulcer may heal spontaneously without external drainage of the abscess is shown by the fact that cicatrization was observed in Leyden's case mentioned above, and in the following, in which the pus escaped through the bronchi or into the pleural cavity.

Case. — Southey [64] reports a case of prolonged pain and vomiting, with tender tumor at epigastrium. Hæmatemesis and melæna. Later, cough and fetid expectoration. Cancer was suspected. Autopsy showed a large abscess between the diaphragm and the left side of the liver, the stomach, and the spleen. Perforation of diaphragm into lung and pleura. A sinus from the abscess led directly to the cicatrix of a round ulcer in the posterior wall of the stomach. No perforation of stomach remained.

Case. (Rigal.)[65] — Man, fifty years old. Sudden attack of epigastric pain, with swelling. Later, signs of pneumothorax. At autopsy, a large abscess between liver, stomach and diaphragm, and on posterior wall of stomach, 4 cm. from pylorus, two recently cicatrized ulcers.

Other similar cases might be cited. Fenwick mentions five, in which, after death, the perforation was found to have healed. In my case, No. II, the same result appeared to have followed the drainage of the cavity, as the offensive vomiting ceased and great general improvement ensued, but the abscess reappeared on the other side, and the patient died. At the autopsy, the ulcer was found closed.

Perhaps, as has been suggested, distention of the stomach ceases after perforation, and this may promote cicatrization. In any event, such a possibility enables us to form a more favorable prognosis in those cases in which posterior intercostal drainage of the abscess is resorted to, or when laparotomy may be undertaken with a view to sewing up the perforation, but when the ulcer proves to be inaccessible. This, I think, from the evidence of the autopsies I have seen, would usually be the case, the adhesions are so extensive and so dense ; and in all operations the danger of involving the general peritoneal cavity must be considered.

In many of the later reports subphrenic abscesses have been diagnosticated promptly, and the necessary surgical procedures have been resorted to. The record of 100 cases, of which 20 were from American sources, shows 20 recoveries. The first cure in Leyden's clinic was in 1882, and most of the successful cases are those in which the operation was for abscesses in the right side associated with the liver or vermiform appendix. As before stated, I find no case of subphrenic abscess caused by perforating ulcer of the duodenum, in which cure has resulted, or in which the perforation has been found cicatrized after death. In but seven cases, when the abscess was under the left ala of the diaphragm and caused by gastric ulcer, has recovery taken place so far as I am aware. One was reported by Barton,[66] in which the abscess opened into the bowel with a discharge of foul pus, and two other cases of spontaneous recovery are mentioned by Leyden.

Case. — Debove and Rémond,[67] at the Hôpital Andral, report the following: A female, aged thirty-three, had had for three years intense gastralgia, hæmatemesis, and epigastric tympany, which extended over the left lobe of the liver. Tapping evacuated foul pus and air, and laparotomy revealed a large abscess behind the liver, with prolongation toward the spleen. Cure in two months.

The author stated that this was the first recorded cure of this condition. But Von Hösslin,[68] from Ziemssen's clinic, has reported a case in which, from the symptoms and the character of the pus, perforation of the stomach was thought to have existed:

Case. — Female, aged thirty years; cyanotic. Respiration, 60; pulse, 120. Left lower ribs motionless. Heart displaced to right. Resection of seventh rib, anterior axillary line, opened a subphrenic abscess communicating with the pleura through an aperture in the diaphragm. During the next day the patient was livid and collapsed, and seemed at the point of death. But she rallied and recovered in seven weeks. A drainage-tube was pushed up through the aperture in the diaphragm and thus the pleural cavity was irrigated.

Scheurlen's case of recovery after resection of a rib is mentioned above, also Renvers's by puncture-drainage, but these are the only other ones which I have found.

Evidently the chance of life is a poor one under any circumstances when perforating ulcer of the stomach or duodenum is at the bottom of the trouble: but when the abscesses are connected with the liver, the kidney, or the vermiform appendix, the outlook is more favorable. These are mostly on the right side,

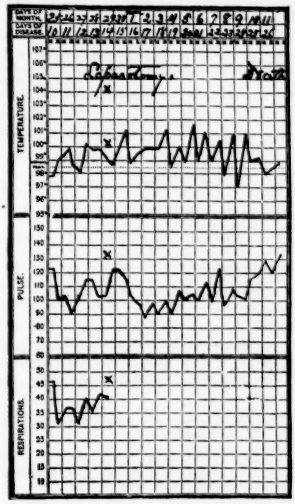
between the liver and the diaphragm, and of such cases recovery took place in thirteen instances, twice by spontaneous evacuation through the bronchi after appendicitis. Resection of a rib was resorted to in a few of these cases only. In the others a simple incision was made. As was stated above, liver abscess is sometimes cured in this manner and should hardly be included in the present subject.

Usually pleural adhesions prevent the opening of the pleural cavity by the knife, but in some cases the diaphragm has been incised through the pleura with a resulting pyo-pneumothorax. In one such instance an epigastric incision was followed by two posterior openings for better drainage. Clear serum flowed, followed by pus. Pyo-pneumothorax ensued, pyæmic abscesses formed in the brain, and death resulted.

This shows the importance of a low incision. The place should be determined by previous careful explorations at more than one level. In those cases in which there is epigastric tumor, laparotomy and search for the ulcer should be resorted to, but posterior drainage, also, will usually be necessary. I can find no record of a successful procedure of this nature. Fitz[69] relates the case of a woman, aged forty-one years, who came to the Massachusetts General Hospital with severe epigastric pain and a history which pointed to a perforating gastric ulcer. He advised laparotomy, but it was persistently refused by the patient, who died. Autopsy showed an abscess below the diaphragm, shut off by adhesions and containing air. The stomach was adherent to the adjacent organs, and had a perforating ulcer on the anterior wall.



The question of "Laparotomy for Perforating Ulcer of the Stomach" is discussed by Weir,[70] who calls attention to the frequency with which this cause of fatal peritonitis is overlooked. In one case he operated, emptied a subphrenic abscess, and sewed up a round perforation half an inch in diameter in the middle of the anterior surface of the stomach near the lesser curvature. The patient died from collapse, having suffered from peritonitis for four days before she entered the hospital.

Most of the ulcers, however, are on the posterior wall and very inaccessible on account of the adhesions. Under these circumstances, Weir recommends making a good-sized hole in the gastro-colic omentum and trying to examine the posterior wall in this way, or making a direct cut of large size into the stomach itself.

This procedure has once come under my observation in the case of a young woman who for three years had presented the symptoms of gastric ulcer. The pain was so great that she insisted on laparotomy, which had been suggested to her. Dr. Bradford incised the stomach and with the electric light examined the interior, but no ulcer could be found. If it had existed, it had healed. But the operation was entirely curative of all the symptoms.

Thus far the results of laparotomy for gastric hæmorrhage have not been very encouraging, and it is improbable that those for perforating ulcer will be more so. But the chance should be taken.[71] In many instances the patients are so exhausted that a prolonged operation cannot be completed. Weir relates such a case, and one came under my observation this year at the City Hospital, in which laparotomy was performed by Dr. Cheever.

CASE VII (Mason). *Perigastric abscess; laparotomy.* A Russian, aged twenty-two years, entered my service at the hospital with severe epigastric pain. In a few days there was a bulging, flat on percussion, at the epigastrium. The heart was displaced to the left. Subnormal temperature. No vomiting. The aspirating needle withdrew, first a clear fluid of strawberry-juice color from the epigastric area, and then several ounces of offensive pus from a deeper level. Dr. D.

CASE VII.

W. Cheever performed laparotomy. The exploring finger discovered a large cavity, with trabeculæ, adjacent to the stomach, but the condition of the patient was such that further examination was not practicable. He rallied, however, and the abscess cavity was irrigated daily. A discharge of sloughy, purulent material continued, pain did not diminish, and he died from exhaustion in two weeks. There was no autopsy, and the cause of the abscess was undetermined.

CONCLUSIONS.

(1) Subphrenic abscess, so-called, is usually due to a circumscribed peritonitis, but may be retro-peritoneal.

(2) The causes are: Perforating ulcer of the stomach, duodenum, or vermiform appendix, rarely of some other part of the intestinal tract; hepatic, peri-hepatic, peri-splenic, and peri-nephritic inflammation; occasionally, gall-stones, cancer, or echinococcus cyst. Sometimes the cause cannot be determined.

(3) Air-containing abscess below the diaphragm, through communication with the gastro-enteric tract, may give rise to signs resembling those of pyo-pneumothorax.

(4) Subphrenic abscess, when dependent upon perforation of the gastro-enteric tract, usually results fa-

tally. But the prognosis is more favorable in those cases which follow perforative appendicitis than in those which result from gastric or duodenal perforation.

(5) The perforating gastric ulcer, which is the cause of the subphrenic abscess, may heal spontaneously after the evacuation of the abscess, and early diagnosis would greatly reduce the hitherto reported large mortality.

(6) Hepatic, peri-hepatic, or peri-nephritic abscess, which presents itself under the arch of the diaphragm, may often be successfully treated by intercostal incision and drainage.

IXODES OR TICK.

BY HAROLD WILLIAMS, M.D., BOSTON.

ALLUSION is sometimes made in medical literature to the ixodes or tick. As they are not often met with in our city clinics, I have ventured to give the following description:

Duhring, in his "Diseases of the Skin," says of them: "There are several species of tick which are met with in our woods and which are liable to attach themselves to the human skin. They insert their proboscis and head deeply into the tissues and suck blood until they not infrequently swell up to many times their natural size. They should never be extracted with violence, but should be induced to relinquish their firm hold upon the skin by dropping upon them some oily substance, as olive oil or one of the essential oils."

Ticks are extremely numerous in Nantucket. I have removed as many as forty from my horses' legs after a single drive. They crawl up the legs of the horses and if left to pursue their course unimpeded, will bury their heads in the thin skin in the neighborhood of the tail or in the interior of the ears. In dogs they usually penetrate the auditory canal, though they sometimes attach themselves in other places. In human beings they almost invariably crawl into the hair at the back of the head or neck, but they sometimes penetrate the ear, where they cause excruciating pain with their hooked feet. They attach themselves to the skin by their jaws and burrow beneath its surface. As they then anchor themselves by their many-barbed tongue they are extremely difficult to remove and upon the employment of traction the body becomes detached leaving the head in the skin to be cast off by suppurative process.

No. I. No. II. No. III. No. IV.

The accompanying illustrations, which are according to exact measurements, were made from a tick which had attached itself to a dog belonging to Alexander Pope, Esq., and were drawn by that artist himself. No. I is a tick as usually seen. No. II is the same tick after five days' feasting upon the thin skin near the ear of Mr. Pope's spaniel. Nos. III and IV are ventral and lateral views of the same engorged tick.

When a tick has penetrated the ear it can be readily and painlessly removed by the use of a ten-per-cent. solution of hydrochlorate of cocaine, olive oil and forceps, in the order mentioned.

Medical Progress.

RECENT PROGRESS IN THORACIC DISEASE.

BY GEORGE G. SEARS, M.D.

(Concluded from No. 9, page 222.)

CROUPOUS PNEUMONIA COMPLICATED BY PURPURA HÆMORRHAGICA.[7]

JAWORSKI has reported the case of a man, twenty-seven years old, who while engaged in making an excavation was seized by a severe chill soon followed by profuse bleeding from the nose and mouth, and loss of consciousness. On the following day the hæmorrhage was repeated several times and in addition pain in the right side of the chest and general weakness and depression manifested themselves. On examination the evidences of croupous inflammation of the middle lobe of the right lung were detected. The skin was rather pale and somewhat moist. Upon the lower part of the body from the umbilicus downward were numerous subcutaneous hæmorrhages varying in size from a pin-head to a lentil. There were also hæmorrhages beneath the conjunctiva into the sclera, and beneath the mucous membrane of the inferior surface of the tongue and lower lip. Neither the gums, palate nor larynx presented any changes or lesions. The tongue was dry and covered with a coating with which coagulated blood was mixed, blood constantly trickled from the nose and there was considerable frothy blood-stained expectoration. The temperature was elevated;

[7] Wien. Med. Presse, xxiv, 3, p. 84; American Journal Medical Sciences, April, 1893.

the pulse full, tense, regular, quickened, the respiration accelerated. The urine was blood-stained and contained red corpuscles. The patient grew rapidly worse and died at the end of five days with signs of exhaustion. The history and the symptoms excluded phosphorous poisoning, arsenical poisoning, scorbutus and typhus fever. No bacteriological investigations were made. The post-mortem examination confirmed the diagnosis of croupous pneumonia complicated by purpura hæmorrhagica.

CREASOTE IN PHTHISIS.[8]

Albu says that we have only one criterion by which we can judge clinically of the effect of a drug upon the progress of phthisis and that is the fever, upon which creasote has no effect; nor among the large number of cases upon which he tried the drug were there any in which the tubercle bacilli permanently and appreciably diminished, while a diminution in their virulence could not be proved by laboratory experiments. He has seen "Phthisis treated with large doses of creasote pursue its course with all the protean changes with which he is familiar; at one time astonishing improvement with permanent subjective sense of well-being; at others, even in the beginning of the disease, a rapid downward course; he has watched the formation of cavities and the progress of amyloid degeneration, the onset of pneumothorax and even death in various stages of the disease"; in other words, he could not see that the course of the disease was appreciably modified, nor was any influence exerted upon the tuberculous process in the lungs. Nevertheless, it is a very useful drug for its symptomatic treatment, as for most patients it appears to be a good expectorant, for others a good stomachic, and it often seems to exert a tonic influence; cure, however, is not obtained by its use.

THE PROGNOSTIC SIGNIFICANCE OF FEVER IN PHTHISIS.

Strümpell[9] considers the prognosis of phthisis in its special relation to fever, which, as a symptom, has the greatest prognostic significance, though other points must be considered, such as the environment of the patient, his heredity, his general make-up, the presence of anæmia or a history of alcoholism. Age is an important factor, as between twenty and thirty the course is apt to be much more rapid than in later life. The previous progress of the case must also be taken into consideration. Encapsulated tuberculous processes occasion no rise of temperature. Although tuberculosis can of itself produce fever, great importance must be attached to secondary infections and diseases, as apart from the symptoms produced by them they render efficient aid to the further extension of the tuberculous process. With fever such secondary processes are almost always present, and thus lead to the spread of the disease.

The author classifies the temperature thus: (1) Subfebrile, with slight evening rise. This form is comparatively benign. (2) Intermittent. Here the disease is progressive, in proportion to the rise in the evening temperature. (3) Remittent, a not very infrequent form in florid phthisis. (4) Continued, seen in the beginning of sudden and acute forms with hardly any abnormal physical signs. After two or three weeks it becomes remittent or intermittent. Such cases usually run a rapid downward course. (5) Irregular. This is generally seen in the third stage, and the cases are mostly unfavorable, especially if high evening temperature and periods of continued fever appear. For months, perhaps, the fever has been hectic, and then it becomes much more irregular. There is then often an increase in the local manifestations of the disease, and in a few weeks death supervenes. Collapse temperatures are also very unfavorable, but there are, of course, exceptions to all these rules.

In speaking of the therapeutics of consumption, he says that the value of remedies can only be tested by their effect on the temperature. He was unable to prove that tuberculin ever caused the fever to disappear, and he had never seen any specific effect from creasote. In all such therapeutic questions the greatest experimental pathologist needs the co-operation of the practical clinician.

A CASE OF PLEURAL EFFUSION AT THE RATE OF THREE AND A HALF FLUID OUNCES AN HOUR.[10]

The following case, reported by Hale White, is remarkable for the great rapidity with which the fluid reaccumulated. The patient had ordinary tubal nephritis, together with mitral constriction and regurgitation, and, as is usually the case, there was some fluid in each pleural cavity which had required tapping. Thirty hours after the first aspiration of the right chest, 106 ounces of serum were withdrawn, which must have accumulated within that time as special pains had been taken to remove all the fluid at the first operation. Seventy-eight hours later 120 ounces more were withdrawn and on this occasion there was extreme pain and dyspnœa and great œdema of the neck, which disappeared after the evacuation of the fluid. Thirty hours after this the chest was again tapped and fifty ounces withdrawn. White can only account for this rapid accumulation by supposing that the patient had thrombosis of the large azygos vein before it is joined by that from the left side. He does not consider it conclusively against this supposition that no evidence of thrombosis was found post-mortem, for the patient did not die till eight weeks afterwards, when all signs of thrombosis might have disappeared. Supposing the fluid collected at a uniform rate, after the first tapping of the chest, that rate was three ounces and a half an hour, after the second, one ounce and a half, and after the third about the same. It is also quite exceptional for the distension of the chest with fluid to be so rapid as to cause acute pain, which is no doubt comparable to that felt in the calf in acute femoral thrombosis, and due to rapid stretching of the parts by fluid; also it must be very rare for the pressure of the fluid on the superior vena cava to cause œdema of the neck.

A Foreign Body in the Ear for Thirty-Nine Years. — A correspondent of the *Medical News* reports the case of a patient who complained of occasional pain in the left ear since childhood. Hearing was almost lost and the canal was filled with a hard substance. With some difficulty a large white bean was removed, with the immediate return of hearing. On questioning the patient it appeared probable that the bean had been in the ear for thirty-nine years.

Reports of Societies.

ASSOCIATION OF AMERICAN PHYSICIANS.

EIGHTH ANNUAL MEETING, AT WASHINGTON, D. C., MAY 30, 31 AND JUNE 1, 1893.

(Concluded from No. 9, p. 224.)

SPORADIC CRETINISM IN THE UNITED STATES,

by WILLIAM OSLER, of Baltimore.

DR. H. C. WOOD thought, that, although cretinism was a rare disease, yet it was more common than appeared from Dr. Osler's paper, because persons have not reported the cases which have occurred to them. He recalled two very positive cases which he had seen in his own experience, entirely outside of any institution.

DR. J. P. C. GRIFFITH thought that what Dr. Woods had said was probably the case. He had seen a case the past winter which had been brought to the Children's Clinic of the University of Pennsylvania. He asked how old the "baby" was, and was told five years. The parents lived at Lancaster, Pa., which is not a mountainous region. There was no nervous disease in the family, and there seemed to be no way of accounting for the child's condition.

SOME PROBLEMS IN THE ETIOLOGY AND THE PATHOLOGY OF TEXAS CATTLE FEVER AND THEIR BEARING ON THE COMPARATIVE STUDY OF PROTOZOAN DISEASES,

by THEOBALD SMITH, of Washington.

The course of Texas fever may be divided into a first stage (acute), and a second stage (mild or relapse) which may follow the first after an interval of two or more weeks. The first is characterized by a high fever and a rapid destruction of red blood corpuscles, amounting to half a million or more per cmm. in twenty-four hours. The second stage, or relapse, differs from the acute fever in its mild, non-fatal course, its fluctuating temperature and a much slower destruction of red corpuscles.

In the acute fever, the number of infected corpuscles which circulate in the blood is small, and rarely exceeds two per cent. The micro-parasite contained in them is fully developed. In the mild fever, or relapse, the number of infected circulating corpuscles is, as a rule, much greater and it may reach fifty per cent. The micro-parasite, in the mild fever, is always in a very young stage in the corpuscle. The probable explanation of this curious phenomenon is a partial immunity of the affected animal acquired in the acute attack, in virtue of which a retardation in the development of the intraglobular parasite is brought about.

The reaction of the organism of the host in the presence of the invasion seems to proceed along lines different from those which are followed during the course of bacterial diseases. While there is a profound disturbance of the system, this seems to be due mainly to the large amount of débris in the blood, which cannot properly be disposed of by the excretory organs. Inflammatory or chemotactic processes are absent and the degenerative changes may be accounted for without assuming the presence of alkaloidal or proteid poisons originating in the micro-parasite.

An important fact which hitherto has not been brought out in the study of infectious diseases is the indefinite persistence of the micro-parasite, in very small numbers, in the blood of insusceptible cattle from the enzootic territory. Such blood is capable of producing the acute disease in susceptible animals. In other words, a complete symbiosis between an otherwise fatal parasite and the host seems to be compatible with and perhaps necessary to immunity.

This disease is probably transmitted exclusively in nature by an ecto-parasite — the cattle tick (*boöphilus bovis*). This important fact opens an interesting and only partly explored field of inquiry in the transmission of human malarial affections.

DR. WM. H. WELCH was quite familiar with the development of Dr. Smith's work, and was extremely interested in the results. The etiology of Texas cattle-fever has become, through Dr. Smith's researches, probably clearer than that of any other protozoan disease. We now know, not only the character of the micro-organism inside the body of the animal, but also the media of development outside of the body, in the cattle tick. Dr. Smith's paper is an important contribution to science, and is an illustration of the value of governmental aid in solving a problem of both scientific and economic importance.

THIRD DAY. — MORNING SESSION.

THE BACILLUS PYOCYANEUS PERICARDITIDIS,

by HAROLD C. ERNST, Boston.

The material from which the bacillus was isolated was fluid drawn from a case of pericarditis. The fluid contained plenty of tubercle bacilli and this new bacillus. With this new bacillus a long series of tests were made upon a large number of different media and under differing conditions of temperature. The only two organisms with which it is likely to be confounded are the bacillus pyocyaneus of P. Ernst and the bacillus pyocyaneus of Gassard. Every step in the investigation of this bacillus was checked by and compared with cultures of the bacillus pyocyaneus derived from four different sources. Dr. Ernst gave in detail the essential differences, both macroscopic and microscopic, between this bacillus and those with which it has been possible to compare it. As the result of these tests, it appears justifiable to conclude that the bacillus is a distinct variety of organism, resembling in many respects the bacillus pyocyaneus but perfectly distinct from it.

DR. A. C. ABBOTT, of Philadelphia, thought that in the bacillus described by Dr. Ernst, we have another addition to make to the group of green-producing micro-organisms. Some of its characteristics are very different from those common to the ordinary green-pus organism: the essential difference between the organism described by Dr. Ernst and the ordinary *bacillus fluorescens liquefaciens*, being the production of the blue-green color upon which Dr. Ernst lays stress.

DR. SMITH had seen all variations in the color-producing power of the saprophyte, and in some cases the color was a very dark green.

GONORRHŒAL MYOCARDITIS.

by W. T. COUNCILMAN, Boston.

There have always been two opinions held about the secondary infections following gonorrhœa; one that they are due to the accidental infection with other organisms which enter through the lesions in the urethra, produced by the disease. Gonococci have been found by various observers in these secondary lesions. Other observers have failed to find them. The most prominent secondary lesions consist of the various joint affec-

tions, of peri-and endo-carditis, and of inflammation of the neighboring lymph glands giving rise to the bubo. Chronic inflammation of the Fallopian tubes in the female is now very generally regarded as due to a previous infection with gonorrhœa. In a case recently seen at the City Hospital there was an acute urethritis, acute inflammation of the joints and an extensive peri- and myo-carditis. Gonococci were found in all of these places. The lesions in the urethra closely similate those described by Bumm in his experimental work on the disease. The gonococci were found only in the superficial layers of the epithelium. In the sub-epithelial tissue there was marked round-cell infiltration. It appears probable from a general consideration of the secondary infections that they are true infections resulting from the presence of the gonococci. In the cases in which organisms have not been found it is very possible that they were so few that the ordinary microscopic investigation would not reveal their presence. That the affection is not due to the presence of pus organisms is shown from the fact that cultures made from these secondary lesions are so generally sterile.

Dr. Reginald H. Fitz had no recollection of ever seeing a case like the one described by Dr. Councilman. Cases of infection through embolism from urethral disease, especially in consequence of surgical operations are not so very uncommon.

Dr. Alfred L. Loomis reported a case which had been very misleading, due to a mixed infection. The patient had gonorrhœa for four or five weeks and then suddenly developed in endocarditis. Within twenty-four hours he had pains in his joints that had not existed before. A relative in the same house at the same time, came down with diphtheria; and in two or three days after the endocarditis, the man had a diphtheritic spot. Had it not been for the occurrence of diphtheria, the endocarditis would doubtless have been ascribed to gonorrhœal origin.

DISCUSSION ON TUBERCULOSIS.

Dr. Wm. H. Welch reported the results obtained in the experimental rabbits given to him by Dr. Trudeau a year ago. There were three rabbits, each inoculated in the same way with a pure culture of the tubercle bacilli, both in the eye and in the pleural cavity. One was a control animal; another was treated with bacterio-proteid; and the third by the filtrate from liquid cultures of the tubercle bacilli. The control rabbit developed a caseous inflammation of the inoculated eye. It went through the typical changes and developed caseous panophthalmitis; all the media became obscure, the cornea became vascularized, and subsequently there was atrophy of the bulb. The animal treated with bacterio-proteid became very emaciated, developed abscesses and ulcerations of the skin in different parts, and finally died without anything to show for the immediate cause of death except the extreme emaciation. There was extensive caseous disease of the eye, but not quite so extensive as in the control animal. The animal treated by the filtrate was of most interest, because the filtrate is said to possess distinct curative or preventive properties. This case turned out just as Dr. Trudeau might have wished. There was no extension of the tuberculous process. There developed a small, grayish-white, slightly opaque nodule at the upper quadrant of the eye in the anterior chamber, which became adherent to the iris, then grew smaller, and finally just a scar was left, without any caseation and without any secondary tuberculosis in the eye which could be determined during the life or after the death of the animal.

Dr. Whittaker said that from some reports made to a previous session of the Society the impression seems to have gone out that tuberculin was not only useless but for the most part actually injurious. Since that time new light has been shed on the nature of the tuberculous process which shows how laboratory tuberculosis differs from human tuberculosis. Dr. Whittaker has administered tuberculin daily since it was first sent out, both in private and hospital practice, and has never seen any reason for a modification of Koch's first opinion as he expressed it in regard to cases of pure tuberculosis. He has observed that under this treatment there has been a singular and early relief from the depressing action of the disease, first of all, and more so than from any other method of treatment. Although a minority of the cases show an exaltation, a *spes phthisica*, yet in most cases there is a marked tendency to melancholy. After five or six injections of tuberculin, patients experience relief from this condition, and they continue to show this relief until some complication occurs. Patients who only have tuberculosis in its inception, having perhaps a light bronchial catarrh at the apices, or are still in the prephysical state of tuberculosis, where we only make the diagnosis by the discovery of the bacillus, when treated with tuberculin are completely rescued in the majority of cases. It does not take so long a time to effect a cure as is commonly asserted. Most of these cases are rescued in two or three months under careful use of the remedy, and these cases do not fall back into the condition of patients who return home from Colorado improved, who fall victims anew to the disease. Tuberculin is the only specific remedy for tuberculosis. All other remedies act only through the avenues of nutrition and resistance to invasion. Where we have mixed infections, as is the case in the later stages of phthisis, tuberculin does little or no good and for the most part harm. It is the reckless administration of tuberculin in these cases of so-called hectic fever that has brought tuberculin into disrepute.

The following officers were elected for the ensuing year: President, Reginald H. Fitz; Vice-President, Wm. Osler; Recorder, J. Minis Hays; Secretary, Henry Hun; Treasurer, W. W. Johnston; Representative on the Executive Committee of Congress of American Physicians and Surgeons, William H. Welch; Alternate Representative, M. Allen Starr; Councillor, John H. Musser.

Drs. George Dock, of Ann Arbor, and T. M. Rotch, of Boston, were elected to membership in the Association.

Recent Literature.

Hand-book of Massage. By Emil Kleen, M.D., Ph.D. Authorized translation from the Swedish by Edward Mussey Hartwell, M.D., Ph.D. 8vo, pp. xvi, 316. With seven illustrations. Philadelphia: P. Blakiston, Son & Co. 1892.

This work comes before us with an endorsement by Weir Mitchell, who states that he knows of no other book on the subject which is so good. In the main

this praise is well deserved. The author has a clear idea of the physiological action of massage, he recognizes, but does not exaggerate its value in certain affections, and his directions in regard to the methods of employing it and to the indications for its use are clear and sound. Frequent personalities detract from the scientific value of the book, although they are at times entertaining. As we seem to be entering upon a season when Swedish gymnasts are in fashion, and as in some instances members of the medical profession have somewhat unwisely endorsed their claims, it would be well for the profession to read the judgment pronounced upon them in this work.

The Disease of Inebriety from Alcohol, Opium and other Narcotic Drugs, its Etiology, Pathology, Treatment and Medico-Legal Relations. Arranged and compiled by the American Association for the Study and Cure of Inebriety. 8vo, pp. xiv, 400. New York: E. B. Treat. 1893.

The Association which assumes the responsibility for this work has adopted as its creed that inebriety is a disease which is curable; that it may be inherited or acquired; that alcohol is a poison; and that inebriate asylums are essential for the cure of inebriety. In support of this creed this volume has been published. Although it has the general endorsement of the Association, and is edited by its secretary, it seems to be the work of various hands, and many of the opinions advanced are without the weight of any personal authority, and anonymous scientific works seldom commend themselves. Much of the work is a compilation from various sources, put together with little method and without judicial weighing of evidence. That inebriety is often a disease few will question, but many of the statements brought forward in support of this view are still questionable, and when, on anonymous authority, we are told that alcoholism and tuberculosis are closely related, because pulmonary phthisis is principally nervous in character, we naturally doubt the scientific value of the work. Inebriate asylums, furthermore, have not yet fully established their value, in spite of the glowing endorsements they receive here. The proof-reading is beneath contempt, and the mechanical execution poor.

New York State Reformatory at Elmira. Seventeenth Year-Book, containing the Annual Report of the Board of Managers for the year ending September 30, 1892. 8vo, pp. 278. With illustrations.

Many men have some vague idea of the methods in use at the Elmira Reformatory, and the results obtained there; but definite knowledge as to the work which has made the institution famous is, we fear, only too rare. At any rate the table showing the state of the reformatory movement in this country is not encouraging. Seven States only have reformatories, and an equal number an indeterminate sentence law, yet Elmira reports, under the New York system, 82.3 per cent. of probable reformations. Beside the ordinary statistical tables this report gives many interesting details of the practical workings of the methods employed in the Reformatory, and it is to be commended to every one interested in the criminal, whether from an anthropological or a sociological standpoint, and to all legislators.

The report is well printed and illustrated, the work being done by the inmates of the Reformatory.

TEXAS CATTLE FEVER, AND THE MODE OF ITS TRANSMISSION.

THE agencies concerned in the transmission of disease are legion. In the vegetable world innumerable means are employed for the propagation of plants — by the aid of the winds, by birds, beasts, insects (as in the transfer of pollen by bees) and by the hand of man. So among animals, including the human race, some diseases are transmitted by direct contact, others by the medium of the breath, others through the alimentary tract, others by inoculation. Certain diseases are capable of transmission from the lower animals to man, and *vice versa.*

After extensive researches as to the natural history of the Texas cattle fever, the Bureau of Animal Industry (Department of Agriculture), at Washington, publishes its belief that an insect closely allied to the tick described by Dr. Williams in this number of the JOURNAL, constitutes a very important agency in promoting the spread of the disease. These researches are published in Bulletin No. 1 of the Bureau (1893), by Dr. D. E. Salmon, Chief of the Bureau, and were conducted, under his direction, by Drs. Smith and Kilborne.

Dr. Salmon, in his introductory letter, says: "The dissemination of the deadly contagion by apparently healthy cattle, and the harmlessness in general of the really sick animals were inexplicable by any facts which were furnished by the study of other diseases. Veterinarians who had not had an opportunity to observe this disease were skeptical in regard to the correctness of such conclusions, and some spoke of them as a 'romance in pathology.' There was an early impression among cattle-raisers that the tick was in some way to blame; but scientists were incredulous, because they could not understand how the bite of these insects could produce an acute disease, accompanied with destruction of blood-corpuscles, and lesions of internal organs. It was not till the micro-organism was found in the blood corpuscles, and its destructive effects were

revealed, that the action of the ticks could be explained."

Experiments were made by the Bureau which demonstrated that the ticks carried the infection, introduced it into the tissues of the susceptible cattle, and in that way produced the disease. In this case there is, therefore, a complicated infection, in which two very different kinds of parasites play an important part.

Another remarkable discovery is that the micro-organism which constitutes the contagion of the disease is transmitted through the egg to the young tick, and it is this, and not the adult tick carried by the southern cattle, which finds its way upon susceptible animals, and causes the disease. In the absence of the tick, the disease is probably not communicable except by artificial inoculation.

The experiments were carefully conducted in isolated fields, and extended over several years' time.

The principal facts established by these investigations are (1) the constant presence of a blood-corpuscle-destroying micro-organism in Texas fever, and (2) the transmission of the disease from cattle to cattle by the tick.

The report embraces chapters on the natural history of the Texas cattle fever, its causation, its transmission by means of the cattle tick, and the immunity of cattle.

The tick which plays so important a part in the transmission of this disease was described by Professor Riley, in 1868, under the name of *Ixodes bovis*, and more recently by Dr. Marx, as *Boöphilus bovis*. It has the general characteristics of the genus, and each female lays from one thousand to two thousand eggs.

The experiments were conducted in three different directions during the period of four years (1889–1892).

(1) Ticks were carefully picked from southern cattle, so that none could mature and infect the ground. The object of this group of experiments was to find out if the disease could be conveyed from southern to northern stock on the same enclosure without the intervention of ticks.

(2) Fields were infected by matured ticks, and susceptible cattle placed on them to determine whether Texas fever could be produced without the presence of southern cattle.

(3) Susceptible northern cattle were infected by placing on them young ticks hatched artificially, that is, in closed dishes in the laboratory.

The report then gives a detailed account of the method of experimentation, together with plates illustrating the diseased and healthy structures, the micro-organisms, the tick in different stages of its growth, and presents the following conclusions as the results of observation and experiments:

(1) Texas cattle fever is a disease of the blood, characterized by a destruction of red corpuscles. The symptoms are partly due to the anæmia produced; partly to the large amount of *débris* in the blood, which is excreted with difficulty, and which causes derangement of the organs occupied with its removal.

(2) The destruction of the red corpuscles is due to a micro-organism or micro-parasite which lives within them. It belongs to the protozoa and passes through several distinct phases in the blood.

(3) Cattle from the permanently infected territory, though otherwise healthy, carry the micro-parasite of Texas fever in their blood.

(4) Texas fever may be produced in susceptible cattle by the direct inoculation of blood containing the micro-parasite.

(5) Texas fever in nature is transmitted from cattle which come from the permanently infected territory to cattle outside of this territory by the cattle tick (*Boöphilus bovis*).

(6) The infection is carried by the progeny of the ticks which matured on infected cattle, and is inoculated by them directly into the blood of susceptible cattle.

(7) Sick natives may be a source of infection (when ticks are present).

(8) Texas fever is more fatal to adult than to young cattle.

(9) Two mild attacks or one severe attack will probably prevent a subsequent fatal attack in every case.

(10) Sheep, rabbits, guinea-pigs and pigeons are insusceptible to direct inoculation. (Other animals have not been tested.)

(11) In the diagnosis of Texas fever in the living animals the blood should always be examined microscopically, if possible.

JEAN MARTIN CHARCOT.

In the death of Charcot, the medical profession has lost a conspicuous figure. Charcot was a prolific original investigator, whose contributions to various departments of medicine have hardly been exceeded by any one of this age. As a clinical teacher, he was one of the most popular on the Continent. He died in the midst of a busy life, but not before suffering from marked diminution of his physical powers. His death was, doubtless, partly the result of overwork, for he habitually took too little rest, as his large private practice was enough to fully tax the strength of any man.

To enumerate his titles and honorary offices, or the titles of his contributions to medicine would require more space than is at our disposal. Besides being connected with the founding and management of three medical reviews, he published over two hundred and fifty memoirs, chiefly pathological, in all of which something valuable was added from his own investigations.

In 1853, Charcot published his thesis for the doctorate, entitled, "A Study of the Affection described under the Names of Primary Asthenic Gout, Nodosities of the Joints, Chronic Articular Rheumatism." His researches in this disease comprehend a vast number of clinical and post-mortem observations made at the Salpêtrière. One of the most important facts brought to light by these researches is that affections of the heart, such as pericarditis and endocarditis, be-

long to the generalized form of chronic articular rheumatism, as well as to acute rheumatism. Another result is to establish an identity between the affection known in surgery under the names of dry arthritis, arthritis deformans, etc., and nodular rheumatism. The separation of gout and chronic articular rheumatism is maintained. He showed that the presence of uric acid cannot be detected in the serum of the blood in chronic articular rheumatism, while in acute and chronic gout the existence of crystals of uric acid has always been recognized.

In a subsequent memoir, he considers the alterations of the kidney observed in the gouty, and gives new researches on the alterations of the joints. Gouty nephritis he believes to be by no means rare, to be attended by deposits of urates in various parts of the kidney, and frequently with the symptoms of renal colic. The lesions may be those of parenchymatous or interstitial nephritis, and the general symptomatology is that of Bright's disease.

Charcot published numerous memoirs on arterial and capillary embolisms at a time when this study was new, and German pathologists were just beginning to give attention to the subject. A *brochure* "On Sudden Death from Obstruction of the Pulmonary Artery by Blood-clots, etc., contains the first observation of death by pulmonary embolism published in France. His paper "On Ulcerative Endocarditis," published in 1862, based on a case of ulcerous affection of the tricuspid valve with typhoid state and the formation of multiple abscesses in both lungs, was the point of departure of an extensive medical literature.

Charcot's contributions to diseases of the lungs constitute two volumes of the new series of his writings. No one now describes the lesions of broncho-pneumonia without referring to his work. In the study of *pneumokoniosis* and *anthracosis* his experiments on guinea-pigs, which were made to inhale in bags mineral or coal dust, gave valuable aids to the comprehension of the pathogeny of a disease often observed in men as a result of occupations exposing them to the action of solid particles diffused in the air. His anatomo-pathological researches on phthisis and chronic pneumonia have furnished valuable data and introduced system where it was before wanting.

His contributions to the subject of diseases of the liver and kidney are embodied in a volume published in 1882. He experimentally determined in guinea-pigs hypertrophic cirrhosis of the liver of biliary origin, and showed its identity with the disease which develops in man as the result of obstruction of the common bile duct. The different stages of the process he divides into angiocholitis, periangiocholitis, cirrhosis. His researches on the common or atrophic form of cirrhosis of the liver are also well known. He, more than any of his predecessors, has insisted on *periphlebitis* as the cause of this affection, and shown the extension of the inflammation from the veins to the connective-tissue. His observations clearly differentiate this form from the other types of interstitial hepatites. Charcot's researches on *grave icterus*, on *interstitial nephritis*, which he was the first experimentally to produce in animals by ligature of one of the ureters, an experiment which showed that the alteration of the epithelium precedes the connective-tissue proliferation, and on the various forms of Bright's disease, may also be noted.

He has also published valuable memoirs on fevers and on cholera, on skin diseases and on exophthalmic goitre, and his "Clinical Lectures on Diseases of Old Age," a work which embodies many of the researches and studies which he had previously made on gout and rheumatism. His contributions to the study of diseases of the nervous system — memoirs and treatises more than a hundred in number — are of great importance. In fact, it is in this department of medicine that he is best known.

Since January, 1882, Charcot held the chair of Clinical Instruction in Diseases of the Nervous System at the Salpêtrière, and gave almost his undivided attention to nervous diseases.

Among his contributions we may mention his clinical and anatomo-pathological researches on encephalitis; his "New Researches on the Pathogeny of Cerebral Hæmorrhage," which contain his description of miliary aneurisms, consequence of endarteritis, and cause of the cerebral hæmorrhages which characterize especially the apoplexies of old age; his studies on secondary degenerations of the spinal cord, on localizations in diseases of the cerebrum, on localizations in the cerebral ganglionic masses of the hemispheres, lesions of the internal capsule in particular; his memoirs on cerebral hemianæsthesia by organic lesion, and on secondary degenerations of the spinal cord in cortical lesions of the hemispheres, showing that lesions of the so-called motor zone even without participation of the internal capsule produces secondary spinal degenerations. We must pass by his valuable contributions to the study of localizations in diseases of the spinal cord. His discoveries in the subject of the *scleroses* alone — locomotor ataxia, multilocular sclerosis, fasciculated sclerosis of the lateral columns, also in the department of infantile paralysis, amyotrophic paralysis of the adult, labio-glosso-laryngeal paralysis, are of the greatest importance.

The modern study of hypnotism is intimately associated with the name of Charcot. His scientific methods of studying the subject, as opposed to the school at Nancy, are well known: in fact, the intimate association of his name with hypnotism has masked the importance of his work in other directions.

THE TENEMENT-HOUSES OF BOSTON.

THE recent report of the Bureau of Statistics of Labor on the sanitary condition of the tenement-houses of Boston shows much to be desired; but it also shows the results of the constant and conscientious work of the City Board of Health. This board suffers from

lack of authority, or divided authority, in dealing with buildings and remedies for existing evils.

The tenement-house population of Boston is continually changing. The worst part of it is composed very largely of foreigners accustomed to dirt; and the houses are often owned by landlords who can only be persuaded to clean up their premises when obliged to by legal authority. Some parts of the city are overcrowded, and in some there is a constant inflow of recent arrivals. On the whole, the health conditions of the city are good, but can only be kept so by continued watchfulness. The report classifies the tenement-houses into excellent, good, fair, poor and bad, in respect to their outside and inside sanitary conditions, ventilation, light and air and cleanliness. A tenement-house is one occupied by more than three families living independently of one another and doing their cooking upon the premises, or by more than two such families above the second floor. 5,992 families, containing 26,097 persons live in tenements classed as being of poor or bad inside sanitary conditions; and 38,311 live in uncleanly places. The percentages for the city show that of persons living in rented tenements about 12 per cent. are found in tenements having poor or bad outside sanitary conditions; between eight and nine per cent. in tenements poor or bad as to light, air and ventilation, and between 12 and 13 per cent. in tenements poor or bad with respect to cleanliness.

The health department has ordered 108 houses vacated during the year, in about three-quarters of which the requirements of the board were complied with within the specified time. In addition 14,079 nuisances were abated, and 872 privy vaults abolished.

The total number of families living technically in tenements is 71,665. Of these, 53,189, containing 228,680 persons, have no bath-room; 5,799 families are dependent on privies; while 65,866 have water-closets; but many of these privies are in the suburbs. 53,831 families have the use of yards; many use them for drying clothes; most of the remainder use roofs; 266 use rooms in the tenement; 4,710 use pulley lines; and a few others use vacant lots. There are 3,657 sleeping-rooms without outside windows.

The report describes the worst parts of the city, many of them being places and alleys technically private, which the street department does not clean. Pressure has in many cases been brought to bear on the abutters; but these private places, and empty lots, and yards of houses require constant inspection, and notification.

MEDICAL NOTES.

The Manufacture of Cripples. — A horrible disclosure has been made in Biskupitz, Austria, by the arrest of a gang of men who for some time have been engaged in crippling children for the begging trade. Several unfortunate children were found in the house with their legs and arms broken and bound in positions of deformity. One little girl had both eyes gouged out. Instruments, which had been used in producing physical deformities, were discovered in the cellar. After the children (who had been stolen) were sufficiently deformed, they were sold to other persons for begging purposes.

Cholera. — The cholera throughout Europe remains unabated. In the East the condition has begun to improve. St. Petersburg has several new cases daily. In Hungary and Galicia the number of new cases each day is over twenty, with a high death-rate. Vienna is, at last reports, free from the disease. No new cases have occurred in Berlin. In Italy the epidemic is well scattered along the coast. Genoa has two or three deaths daily. Alessanchia, Messina and Catania are all infected; while in Palermo there are about thirty new cases daily. In Leerdam and Rotterdam where the cholera appeared August 25th, there are now nine or ten new cases daily with about five deaths. In England the port of Grimsby, Lincolnshire, has been declared to be infected with cholera, and traffic between it and other British ports has been prohibited. During August there were eighty deaths in Grimsby from what was called at first diarrhœa, and later a choleraic disease. The general belief now is that many of these deaths were due to cholera. Several deaths from sporadic cholera occurred last week in Jersey City, and occasioned some alarm. In two cases the dejecta contained spirilla.

NEW YORK.

Cholera in Jersey City. — It has as yet been found impossible to trace the origin of the unexpected occurrence of cholera in Jersey City. As soon as the suspicions of the members of the Board of Health of that city were aroused they called upon the Health Department of New York to assist them, and the bacteriological investigation made by Dr. H. M. Biggs, Chief Inspector of Pathology, Bacteriology and Disinfection, showed that the disease was true Asiatic cholera. Since then the officers of the Jersey City Board of Health, the New Jersey State Board of Health, the New York Board of Health, the United States Marine-Hospital Service, and the New York Quarantine Department have been in constant conference with a view to preventing the occurrence of other cases.

Mortality. — The State Board of Health reports that the average daily mortality during the month of July (in which the death-rate is always larger than in any other month), was 398, against 437 last year. The health of the city of New York continues exceptionally good for this season of the year. During the week ending August the number of deaths reported was 752; which is a decrease of 53 compared with the mortality of the preceding week and 71 less than the average of the corresponding weeks during the past five years. The number of deaths of children under five years of age from diarrhœal diseases was only 88, and this is 47 below the average of the corresponding weeks of the past five years.

ACTIONS AGAINST DRUGGISTS. — Two infants have recently died in Brooklyn from the effects of medicines illegally prescribed by druggists, and proceedings have been instituted against the latter. An action for $10,000 damages has also been brought against one of these druggists in another case. The plaintiff alleges that his five-year-old daughter, having broken her arm, was taken to the defendant's drug-store, and that a liniment was prescribed under the idea that the injury was merely a sprain. For ten days or more this was used, but the arm finally became so swollen that the child was taken to the Brooklyn City Hospital, where it was ascertained that a fracture had occurred. By this time the bones had united in such a way as to cause a marked deformity, and it became necessary to fracture them over again and reset the fragments.

A CASE OF LONGEVITY. — Mrs. Ann Hyde, according to the last census the oldest woman in New York State, died at her residence at Fishkill on the Hudson, August 28th, at the age of 104 years and four months. She was born at Fishkill, April 28, 1789, and as her name is on the baptismal register of the old Dutch church in that village, there can be little doubt about the correctness of her age.

Miscellany.

"THE NEW ACQUAINTANCE."

IN an article in a recent number of *Blackwood's* on "Scottish Medicine in the days of Queen Mary" there is an interesting account of one of the earliest epidemics of influenza. In November, 1562, Mary, Queen of Scots, was taken ill with a disease which had appeared suddenly and was widespread, exciting much curiosity among the people by reason of its novelty. Thomas Randolph, an emissary of Elizabeth at the Scotch court, wrote to Lord Cecil as follows:

"May it please your honor, immediately upon the queen's arrival here she fell acquainted with a new disease that is common in this town, called here the New Acquaintance, which passed through her whole Court, neither sparing lord, lady nor damoiselle — not so much as either French or English. It is a pain in their heads that have it, and a soreness in their stomachs with a great cough that remaineth with some longer, with others shorter time, as it findeth apt bodies for the nature of the disease. The queen kept her bed six days; there was no appearance of danger, nor many that die of the disease except some old folks."

THE WILLIAM F. JENKS MEMORIAL PRIZE.

THE trustees of the College of Physicians of Philadelphia will award the third triennial prize, of five hundred dollars, under the Deed of Trust of Mrs. William F. Jenks, to the author of the best essay on "Infant Mortality during Labor, and its Prevention."

The conditions annexed by the founder of this prize are, that the "prize or award must always be for some subject connected with Obstetrics, or the Diseases of Women, or the Diseases of Children"; and that "the trustees, under this deed for the time being, can, in their discretion, publish the successful essay, or any paper written upon any subject for which they may offer a reward, provided the income in their hands may, in their judgment, be sufficient for that purpose, and the essay or paper be considered by them worthy of publication. If published, the distribution of said essay shall be entirely under the control of said trustees. In case they do not publish the said essay or paper, it shall be the property of the College of Physicians of Philadelphia."

The prize is open for competition to the whole world, but the essay must be the production of a single person.

The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U. S. A., before January 1, 1895, addressed to Horace Y. Evans, M.D., Chairman of the William F. Jenks Prize Committee.

Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The Committee will return the unsuccessful essays if reclaimed by their respective writers or their agents, within one year.

The Committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

LEGISLATION FOR THE PREVENTION OF BLINDNESS FROM OPHTHALMIA NEONATORUM.

IN the present day of prophylactic medicine no disease offers a more encouraging field for sanitary legislation than does ophthalmia neonatorum. A disease which causes yearly an enormous number of cases of permanent blindness, being undeniably a preventable one, should not escape strict control. Statistics from the various asylums of Europe and America show that an average of twenty-four per cent. of all cases of blindness are due to contagious ophthalmia of the new born. Prince[1] shows by a study of collected cases the indisputable fact that the percentage of cases of ophthalmia of inter-partum origin has steadily diminished under improved methods of obstetrical cleanliness. Of the cases which do occur, the number permanently injured has decreased even more since the importance of immediate care has been made generally known.

Much still remains to be done, however, both by missionary distribution of literature on the subject, as is done by the Hungarian, Austrian and French Governments, and by actual legislation by our States. Switzerland, in 1865, was the first country to take action, with the proud result that Professor Horner could say that during his lifetime no child born after 1865 was admitted to the Blind Asylum at Zurich with sight lost from ophthalmia neonatorum.

In this country New York and Maine passed laws requiring midwives to report reddened or inflamed eyes of children under their care within six hours, under penalty of fine or imprisonment. Bills to effect the same purpose have been introduced this past winter

[1] New York Medical Record, August 26, 1893.

in the Legislatures of Ohio, Pennsylvania, Minnesota, Illinois, and the Dominion of Canada.

A subject of so much importance ought not to be neglected longer in any State which claims to have an interest in the welfare of its children.

Correspondence.

[From our Special Correspondent.]

LETTER FROM PARIS.

PARIS, August 18, 1893.

MR. EDITOR: — Only the pleasure of writing to the JOURNAL could induce one to make any great exertion to-day, with the thermometer at 95° Fahrenheit, in the shade, and not a breath of breeze. I have been waiting to go to the Salpêtrière until I can safely do so without sunstroke, and now Charcot is dead. The medical profession of Paris, of the world, has lost two great representatives this week, two men quite unlike in outward manner, but at heart equally enthusiastic for medical progress.

The brilliant extent of Professor Charcot's work, especially the almost dramatic results of hypnotism, have been the theme of all the papers for the last few days. The *Figaro* says that, "though in time the world may have lost all recollection of his work on locomotor ataxia, of his researches into the nature of hysteria and neurasthenia, and many have forgotten that he suspended tabetics that they might live, and that (without metaphor) he sold — dearly — wisdom to dements, there is one thing it can never forget, that he could drive out evil spirits and could calm perturbed souls, and that from all quarters of the world, where his word was as law, the worn and shattered mind turned to him as to a very miracle-worker and a savior."

Of all his work, the researches into hypnotism are here considered the great glory of his life and of modern medicine. His clinic at the Salpêtrière was called the "rendezvous and heart of the medical world." Doubtless his work will last; but it is exposed to great danger of change and evil, for in such a specialty there is a subtile distinction to be kept between medicines and charlatanry. This distinction Charcot maintained with the most delicate and appreciative tact, kept his work up to the standard of scientific research in spite of all attempt to degrade it to empiricism.

He was at times reproached, and not perhaps without some semblance of truth, with an unmeasured pride, a personality which was unabashed and assertive, and a love for applause which bordered upon the theatrical; but no one ever questioned his genius. "Great as his renown in France, it was here that he held the lowest place of all his glory; for at Dorpat as at Jena or Edinburgh or Berlin, at Vienna as at New York, his word was as law to the initiated."

A distinguished scholar, a wise observer, a prudent and sagacious clinician, often a bold experimenter, Charcot exercised an influence upon contemporary medicine as great as it was salutary. Discussing with a remarkable insight and breadth of view each new idea as it was advanced, he was an incomparable teacher. He died in the fulness of his powers; and with him there vanished one of the strongest personalities of this age.

Antoine-Emile Blanche was less known abroad, but his place will be even harder to fill than Charcot's. The son of a noted physician, he inherited an aptitude for the care of the sick which was little short of marvellous. A warm and generous nature which went out in sympathetic tenderness to the suffering, coupled with unusual strength of will and purity of character, made him particularly fitted for his specialty as an alienist. His private asylum at Passy was the retreat of many noted men. "He gathered the wounded in the battle of poetry, of romance, of the drama or of daily life, and carried them tenderly away to care for them, and cure if possible, upon his hill of Montmatre. No one might know the names of the patients of Dr. Blanche. He was the first to keep silent the name of him he saved; and as he kept the secret of those who died, he kept the harder and more sacred secret of those who lived. He passed silently and without recognition the patient he had cured. Once they returned to the walks of men, he ceased to know them."

A wise and good physician, he corrected theory by observation; fully abreast of the times in his scientific knowledge, he was always conservative in practice. His patients were not so much pathological studies as they were human beings and he more than once expressed a fear that "the brilliancy of new methods might make men forget somewhat the old, which consisted in *pity* for the sick." The regret for his death has been widespread and sorrowful — a personal grief, as it were, for the loss of a warm friend, a generous giver, a tender, wise and just physician.

Last year much joy was given to the Parisians by a man with a musical anus. This year medicine supplies the curiosity. At the close of the Congress for the Advancement of Science the members of the Section of Medicine had a banquet. At dessert the "venerable Dr. Schiff of Geneva, who presided," entertained the company by playing the *Marseillaise* with the abductor muscles of his feet. Strong rhythmic contractions produced a sound audible for two or three metres. He is said to be the only possessor of this accomplishment in society, which, however, does not prevent him from being a gallant gentleman and a scholar — *Au contraire!*

The health of Paris has been unusually good this year, notwithstanding the great heat, which has now lasted almost uninterruptedly for two weeks, and prevailed previously with interruptions. This heat has been accompanied by prolonged dryness, which has seriously injured all crops except the fruit crops. A remarkable yield of grapes is looked for, and experts expect a very fine year for wines. There has been no cholera in Paris or its neighborhood, and no occasion to avoid the city on account of that disease.

The new water-supply is of excellent quality, though not yet entirely sufficient in quantity. There are very few strangers in the city, and Americans are conspicious by their absence. Yours truly, S. E.

MEDICAL WITNESSES.

DORCHESTER, September 1, 1893.

MR. EDITOR: — Judge Hammond remarks, on expert testimony, as he is quoted in the Boston *Medical and Surgical Journal*:[1] "The physician is often hampered by the stupid questions of the lawyer, who frequently puts on so many conditions that it may be impossible to answer many of his questions, and no attempt should be made to do so in the form in which they are presented."

This calls to my mind a case in which I once appeared before a coroner's jury, together with the late Drs. J. B. S. Jackson and C. C. Holmes, of blessed memory. The case was one which was of much public interest at that time. A young man had been severely beaten by a jealous husband. He came home bruised in body, and mortified in spirit, took cold, had a sore throat, and died. After the post-mortem, Dr. Jackson said: "Who can say that the beating caused this young man's death, and who doubts that, if he had not been beaten he would be alive to day?" The coroner with his jury (nearly all of them named Tucker, with Captain Elijah as foreman, if I remember aright) was waiting for the result of the autopsy. The coroner was a very excellent and intelligent gentleman (and, withal a good judge of a horse), but the situation in which he found himself was new to him. One who has listened to medical testimony can well understand how, with an inexperienced coroner, the more talk the more confusion of ideas on the part of the jury. Such was the condition of affairs when Captain Elijah, impatient at the multitude of words, exclaimed, "What *killed* the man? That's the pint."

If the lawyers would ask questions to the *pint*, we should not hear so much complaint of medical experts. C.

Deaths reported 3,069: under five years of age 1,615; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 913, diarrhœal diseases 638, consumption 316, acute lung diseases 180, diphtheria and croup 107, typhoid fever 63, whooping-cough 29, cerebro-spinal meningitis 23, scarlet fever 22, measles 17, malarial fever 9, erysipelas 3, small-pox 2.

From whooping-cough New York 9, Chicago 7, Philadelphia and Brooklyn 3 each, Cincinnati 2, Boston, Washington, Nashville, Cambridge and Haverhill 1 each. From cerebro-spinal meningitis Chicago 7, New York 5, Brooklyn and Washington 2 each, Philadelphia, Cleveland, Worcester, Lynn, New Bedford, Gloucester and Waltham 1 each. From scarlet fever New York 6, Chicago and Boston 3 each, Philadelphia, Milwaukee and Cambridge 2 each, Brooklyn, Worcester, Lynn and Woburn 1 each. From measles New York 11, Brooklyn, Washington, Milwaukee, Worcester, Springfield and New Bedford 1 each. From small-pox New York and Chicago 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,322,429, for the week ending August 19th, the death-rate was 22.8. Deaths reported 4,515; diarrhœa 629, whooping-cough 100, measles 92, diphtheria 81, scarlet fever 78, fever 76, small-pox (Bradford 4, London 3, West Ham 2, Birmingham 1) 10.

The death-rates ranged from 13.6 in Halifax to 33.1 in Preston; Birmingham 22.0, Bradford 17.6, Croydon 24.4, Hull 31.0, Leicester 25.2, Liverpool 27.1, London 22.5, Manchester 23.2, Newcastle-on-Tyne 18.3, Nottingham 21.5, Portsmouth 19.3, Sheffield 25.8, West Ham 25.2.

AN ARMY MEDICAL BOARD

Will be in session at Washington City, D. C., during October, 1893, for the examination of candidates for appointment to the Medical Corps of the United States Army, to fill existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before September 15, 1893, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character and moral habits. The candidate must be between twenty-two and twenty-eight years of age and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

GEO. M. STERNBERG, *Surgeon-General U. S. Army.*

MASSACHUSETTS MEDICAL SOCIETY.

CENSORS' EXAMINATION.

The Censors of the Suffolk District Medical Society, officiating for the Society at large, will meet for examination of candidates for admission to the Massachusetts Medical Society, at 19 Boylston Place, on Thursday, September 21, 1893, at 2 P. M.

Candidates should make personal application to the Secretary on Mondays or Thursdays, from 2 to 3 P. M., or at the time and place of the examination. They must bring their medical diploma or a certificate that they are entitled to one, with them.

JAMES J. MINOT, M.D.,
188 Marlborough Street. *Secretary.*

RECENT DEATHS.

DAVID SYLVESTER FOGG, M.D., M.M.S.S., died in Norwood, August 30th, aged seventy-two years.

ADONIRAM J. GREELY, M.D., died in Providence, R. I., September 1st, aged seventy-five years.

BOOKS AND PAMPHLETS RECEIVED.

The Successful Treatment of Typhoid Fever. By Charles Milton Buchanan, M.D., Washington, D. C. Reprint. 1893.

A Manual for Boards of Health and Health Officers. By Lewis Balch, M.D., Ph.D. Albany, N. Y.: Banks & Brothers.

Report of Four Hundred and Sixty-Six Cases of Intubation of the Larynx. By F. E. Waxham, M.D., Denver, Colo. Reprint. 1893.

Tenth Annual Announcement of the Medical and Dental Departments of the National University, 1893-94, Washington, D. C.

Observations on a Case of Recurrent Amœbic Dysentery with Successive Large Hepatic Abscesses. By John Winters Brannan, M.D. Reprint. 1893.

Transactions of the New York State Medical Association for the year 1892. Vol. IX. Edited for the Association by Ogden C. Ludlow, M.D. New York. 1893.

Transactions of the Medical Society of the State of Pennsylvania at its Forty-Third Annual Meeting, held at Williamsport. Vol. XXIV. Philadelphia: Published by the Society. 1893.

A Manual of Medical Treatment or Clinical Therapeutics. By I. Burney Yeo, M.D., F.R.C.P., Professor of Therapeutics in King's College, London. In two 12mo volumes containing 1275 pages, with illustrations. Philadelphia: Lea Brothers & Co. 1893.

Lecture.

THE MISUSE OF DRUGS IN MODERN PRACTICE.[1]

BY JOHN T. G. NICHOLS, M.D., OF CAMBRIDGE.

(Continued from No. 10, page 242.)

Of late years, the value of drugs in the treatment of disease has been asserted with increasing vigor. I have already spoken of the number of new remedies which have been brought to our notice of late years. I quote from an article on "Progress in Pharmacy," by John Aulde, M.D.:

"Alkaloids and synthetic remedies practically rule the field, and the pharmacist finds his sphere limited principally to preparing these powerful concentrated remedies into convenient forms for administration. It has been a decade of enormous progress, and the resulting disquietude of the transition period is not yet allayed. New remedies are introduced day by day, without a sign of abatement in the inventive and creative art of the chemist. . . . It is a safe estimate to claim that one hundred new remedies of synthetic origin, which were not known ten years ago, are now in general use, and the number is daily increasing."[8]

But it is not necessary to multiply authorities. One has only to turn over the pages of our medical journals to be convinced of the truth of this statement. New remedies are announced almost daily. We read of new uses for the same remedy, new remedies for the same uses, until we wonder, as the layman must, as he reads the medical advertisements in the daily papers, that our bills of mortality are still so high.

Have we reason to believe that we have made substantial gain in our power to control disease by this great addition to our list of remedies?

It was held by Bigelow and his supporters that most acute diseases were self-limited, and could be influenced only slightly, if at all, by drugs. "By a self-limited disease," he says, "I would be understood to express one which receives limits from its own nature, and not from foreign influences; one which, after it has obtained foothold in the system, cannot, in the present state of our knowledge, be eradicated or abridged by art; but to which there is due a certain succession of processes, to be completed in a certain time; which time and processes may vary with the constitution and condition of the patient, and may tend to death, or to recovery, but are not known to be shortened or greatly changed by medical treatment."[9]

Nearly sixty years have passed since these words were written. With all the activity in the study of therapeutics, with all the new medicines which have been added to our list, can this definition be disputed or materially changed? Certainly not, as far as the epidemic diseases are concerned which from time to time make their appearance with such fatal results. The fatality of the recent epidemic of cholera in Europe, amounting to about fifty per cent., shows no gain in our power to control it. The same thing may be said of yellow fever. If we have made any progress in our treatment of small-pox, it has been by following the methods of rational medicine, and trying to support the patient while the disease goes through its regular succession of processes.

Diphtheria is a disease which many of us still in active practice have seen in its commencement and spread. Its average death-rate of about one-third shows that no medicine has yet been found which can materially influence its course. On the other hand, when we examine the properties of many of the drugs which have had a wide use, we cannot escape the conclusion that the patient has often had to contend with the remedy, as well as with the disease. In a recent discussion in the New York Academy of Medicine, Dr. E. H. Janeway said "he had no doubt that a certain number of people, said to die of diphtheria, in reality died of the remedies given against the disease."[10]

Epidemic influenza tends strongly to recovery. Its results, immediate and remote, are determined by the constitution and condition of the patient. Various as are the drugs which have been given in this disease, good as are the results which have been claimed for them, there is no drug treatment upon which the profession is agreed as materially influencing it.

The result of the tabulation of one thousand cases of acute lobar pneumonia, treated in the Massachusetts General Hospital from 1822 to 1889, is thus stated by Townsend and Coolidge: Twenty-five per cent. of the cases were fatal. Treatment was heroic before 1850, transitional between 1850 and 1860, expectant and supporting since 1860. There is no evidence that the duration, length of convalescence or the fatality have been modified by treatment.[11]

Acute rheumatism is a disease, which if our art has not subdued, it is not for want of effort. To enumerate the drugs which have been used in this ailment would far exceed the limits of this address. More than once have sanguine hopes of a remedy been raised, soon to fade before experience. Of late years, salicylic acid and allied drugs have held the first place. It may be questioned if we have gained as much from them as many believe. These medicines relieve the pain, and lessen the fever more rapidly than any others of which we have knowledge. But relapses are more frequent than under other modes of treatment. The cardiac complications are quite as common as under any other treatment. They have no power either to prevent or to overcome the most dangerous symptom of this disease, hyperpyrexia. The duration as shown by length of stay in hospital is not materially lessened. The untoward effects of these drugs are common, often serious, sometimes fatal.[12] When we remember that these results are mainly drawn from experience in hospitals where patients are usually taken from bad, and put under good conditions, we must admit that the modern drug treatment is, at best, one of alleviation, and that this result is not gained without a considerable risk.

No drug has been found, even in the long list of synthetic medicines, which materially modifies the course or changes the result of typhoid fever. If figures are to be trusted, the only agent which may do this is cold water. If it be said that this is a drug, considering the use to which it is put, it is one which has no hurtful properties in itself, which can be safely, if judiciously, used, and which the pharmaceutist cannot utilize for purposes of gain.

The most trivial of acute diseases is coryza, com-

monly known as "a cold in the head." Its diagnosis is easy, its natural history well known. Its local manifestations are within sight. If drugs have power to abort or shorten disease, we should find proof of it here. Belief in their power is abundant, evidence of it is wanting. The harm that has been done by attempts to influence this disease will not be questioned by any one who has seen cocaine poisoning, or has had to treat the cocaine habit. Aurists tell us that the massive doses of quinine often used, may set in motion a train of pathological processes which have fatal possibilities. If we cannot do a little thing with drugs, we may well doubt our power to do a great thing. If we cannot cure a cold in the head, let us be modest in claiming the power to cure diphtheria.

Turning to the subject of chronic diseases, the name itself implies the inadequacy of our art to shorten them. Cures for consumption have abounded in the history of medicine. Our own time has given birth to many, yet it is generally fatal. Cures for cancer, even, have not been unheard of, yet its prognosis remains unchanged.

Dyspepsia, which has been called our national disease, still maintains its foremost position, in spite of the use of pepsin (so large that some of the great meat-packing houses have found profit in putting it on the market), and the multitude of digestive ferments with which the enterprise of our pharmaceutists has furnished us. The pithy prescription of a member of this Society, long since gathered to his fathers, "drink the hundredth stroke of the pump before breakfast," and the still more comprehensive one of Abernethy, "live upon sixpence a day, and earn it," [13] have cured more cases of dyspepsia than all the pepsins and triferments of the druggists' circulars.

As we turn the pages of the mass of literature on nervous diseases, a sentence from the first aphorism of Hippocrates occurs to us: "Life is short and the art long." Studying the drug treatment of these disorders, we find little to convince us that the good it may do is not counterbalanced by its possible influence for harm.

Among the new drugs which have been brought into use of late years, those supposed to have a tonic or stimulant effect upon the heart hold an important place. In acute disease, as the heart shows supposed weakness, one, often several, of these powerful medicines are advised, while in diseases of the heart itself they find their greatest field of action. That they may often be of service no one will deny. That they may do harm, no one who studies their toxic properties can doubt. That their power for good is limited is at least suggested by the fact that, since their multiplication, "heart-failure" appears with increasing frequency in our certificates of the cause of death.

The numerous synthetic drugs, of which the most largely used are antipyrin, antifebrin and phenacetin, have wide applications in disease, if one may believe all he reads about them. Prof. H. A. Hare says of these three drugs:

> "They have relieved an amount of human misery, resulting from painful manifestations of functional or organic nervous disease, which it is not in the power of the human mind to estimate, and this, too, in most cases, without any ill effects such as follow the opiates. . . . Nor have these products proved themselves limited to any one class of cases. They have proved a perfect wonderland of useful application, and there is certainly no drug ever discovered which is so universally applicable as antipyrin, the powers of which are almost as diverse as disease itself." [14]

The young practitioner, reading this statement by a teacher of therapeutics in a leading school, must feel that a panacea is almost found. Filling his pocket-case with these drugs, he goes on his way rejoicing in his power to relieve and cure. If he gives them to every patient who complains of pain, and attributes the relief to the drug, he will, for a time, be a happy man. It will not be long, however, before he meets with cases where the expected relief does not come. If he observes carefully and honestly, he will see harmful results in not a few cases. He is fortunate if he does not get thoroughly frightened by the effects of his remedies before long.

Let us examine the power of these drugs for harm. I take the facts which prove it from an essay by the same man who praises their power and safety so highly, to which was awarded the Boylston prize of Harvard University in 1890. I can give only a brief statement of the subject, referring those to the essay who prescribe these drugs without fear of consequences.

Antipyrin. 127 cases of untoward effects; 8 deaths; result not stated in 14 cases.

Antifebrin. 38 cases of untoward effects; 3 deaths; result not stated in 1 case.

Phenacetin. Three cases of untoward effects; no death.

Summing up these figures, there are one hundred and fifty-three cases in which the result is stated. Eleven were fatal, or about seven per cent. It is true that in most of the fatal cases the result was largely due to the disease for which the drug was given. It may be fairly said, however, that the chance of recovery was lessened by the disturbance caused by the drugs.

The serious character of the untoward symptoms recorded in these tables is shown by the fact that collapse, often described as "severe," "alarming," "profound," occurred in fifty cases; cyanosis in thirty-one; disturbance of the heart's action in eighteen; dyspnœa in nine; a purpuric state in seven.[15]

To determine correctly the effect of drugs in disease is one of the most difficult questions which the practitioner of our art has to meet. Experience is the source of nearly all the knowledge we have to aid us in answering it. Science has told us how some drugs, which experience has approved, produce their favorable effects; but the day of a scientific system of administering drugs has not yet arrived.

An accurate diagnosis is essential to trustworthy experience. Errors upon this point are the cause of many of the uncertain and contradictory conclusions which have been drawn from experience. Diagnosis is seldom easy, often doubtful, sometimes impossible. Having made a correct diagnosis, we must know the natural history of the disease. We cannot know the effect of a medicine in a disease unless we also know what will be its duration, the order of succession of its symptoms, and the probable result, uninfluenced by drugs. We must know the probable cause of the disease, for we cannot draw a fair inference as to the usefulness of a drug if the cause is still in operation. We must also know the action of drugs upon the system in health, and how to apply them correctly in

[13] Physic and Physicians, Philadelphia, 1845, Part i, p. 98.

[14] International Medical Annual, 1893, New York and Chicago, p. 4.

[15] Fever: its Pathology and Treatment by Antipyretics, by Hobar Amory Hare, M.D., etc., Philadelphia and London, 1891.

disease. We have all these facts in very few cases; in many cases we have certain knowledge of none of them. Ignorance of any one of the factors of the problem gives a wrong answer. To assert the value of a drug in phthisis, where it has been given in a case of catarrhal inflammation of the lungs, to ascribe the improvement which nature effects at the crisis of pneumonia to the medicine given at the time, to proclaim the efficiency of drugs of which we know so little as we do of many of the new ones which are daily brought into use, are examples of the errors which make experience so fallacious. To give drug after drug, perhaps the very one which has caused the disorder, to a patient suffering from chronic poisoning by arsenical wall-paper, is mortifying to the doctor, and calculated to bring the art into contempt with the patient.

The constitution and condition of the patient must also be taken into account. The tendency to disease, hereditary or acquired, the power of resisting its causes, the influence of surroundings, must be known before we can judge correctly as to the influence of drugs.

Even if the mass of recorded experience was that of competent observers, the question is so beset with difficulties that the answer must be a doubtful one. But, especially of late years, those men whose opinions are most to be valued have not much to say about the use of drugs. As I meet such men in consultation, I find that while they are careful in diagnosis, painstaking in investigating causes, attentive to the surroundings of the patient, they are cautious about advising powerful medicines. I think most thoughtful men will say that, as they grow older, they put less trust in drugs.

But much of the so-called evidence in favor of the usefulness of drugs is drawn from the reports of men whose argument is *post hoc, ergo propter hoc*. Not careful in diagnosis, undervaluing the power of nature, influenced by authority or the fashion of the day, they are always ready to try new remedies, and quick to report their supposed successes. They do not apply this argument to their failures. Often they do not report them, in which case their testimony is worse than worthless; it is misleading and dangerous. Some, too honest to conceal the truth, report their unfortunate results, but ignore the possible effect of drugs in determining them, offering some plausible explanation of them. We often read something like this: Dr. —— has treated twenty-two cases of typhoid fever by a certain drug, with twenty recoveries. Of the fatal cases, one was moribund when the treatment was begun, the other died of perforation of the intestine. "There are some people," says Paget "who seem to have a happy art of forgetting all their failures and remembering nothing but their successes, and as I have watched such men in professional life, years have always made them worse instead of better surgeons. They seem to have a faculty of reckoning all failures as little and all successes as big; they make their brains like sieves, and they run all the little things through, and retain all the big ones which they suppose to be their successes; and a very miserable heap of rubbish it is that they retain." [16]

The average patient listens with much more interest to the prescription of his physician than to his directions about his hygiene. Expecting good results from the drug, he often imagines that he feels them. So great is the power of hope that, even in incurable diseases, a temporary improvement often follows each new prescription. This power of hope is one of the chief articles of the materia medica of the quack. It is sometimes used by the educated physician, who calls it "expectant attention." From a recent system of therapeutics I quote extracts from an article written by a professor of therapeutics in one of the leading schools of the country:

"The physician who fails to avail himself in disease of the 'expectant attention,' drops one of the most important articles out of his list of medicinal agencies. . . . When a resident physician in the Philadelphia Hospital years ago, in charge of a large ward of women, I habitually used a solution labelled 'morphine,' which contained none of that alkaloid, but just enough quinine to make it conform in taste to the knowledge of the habitués of the institution, and in three cases out of five it aided in bringing comfort and rest, as well as did the genuine morphine solution. Some time ago, I gave a patient, with very minute and emphatic instructions as to the method of use, a prescription for pills of bread. Several months after, she came back to me and said, 'Doctor, why did you not give me that prescription sooner? It is the only thing that has reached my case, and I have had that prescription filled at the apothecary's for a number of my friends, with extraordinary results.'" [17]

The pharmaceutists give us a hint as to how far this sort of teaching has influenced our art, when they offer us the means to carry out such treatment. Within six months, the agent of a large manufacturer of "tablet triturates" offered me "blank tablets." The name he gave them will interest many of this audience. It was "Harvard Experimental Diagnosis Tablets." Setting forth their value to me from a business point of view, he told me, untruthfully I hope, that he had just sold five thousand to a physician in my own town. There can be but one opinion among honest men about this practice. It not merely weakens the distinction between the regular practice of medicine and the practice of quackery; it destroys it; it *is* quackery.

The germ theory of disease is passing beyond its first stage, and is taking its place as a real addition to the science of medicine. It has rendered great service to the art by adding to the power of preventive medicine. It has not done much for the drug treatment of disease. If it is believed that infectious diseases are caused by germs, introduced from without, the inference that drugs which kill them outside the body may destroy them after they have got in, is so attractive that it has led to many experiments in this direction. Drugs of highly poisonous properties have been largely used with this end in view. That harm has resulted from these experiments there can be no doubt. There is good reason to believe that in the hands of men who make facts suit their theories, life has been endangered, and even destroyed, by the reckless use of these drugs. No efficient and at the same time safe drug is now known which can destroy the germ within the system. The efficient germicides are dangerous, the safe ones are uncertain. It is too soon to say what advances in the use of drugs may result from the germ theory in the future. It may be that disease will yet be prevented, or even cured, by injecting substances into the system which may kill germs, directly or indirectly. It may be, to use the words of a believer in this hopeful prospect, that "the future of scientific medicine is in this direction, and that we have entered upon a field

[16] Clinical Lectures and Essays, London, 1875, p. 74.

[17] A System of Practical Therapeutics. Philadelphia, 1891, vol. i, pp. 41, 42.

that is to be cultivated vigorously, and which will give you results that will knock the conservatism from under your feet before many years." [18] Conservatism always will be a solid foundation for the practice of medicine. The memory of tuberculin is too recent to allow us to forget that a great man may reduce his theories to practice prematurely, and so shake the confidence of the public in our art.

It is my belief that nothing has done more to encourage reliance on drugs than the narrow definition which is given to materia medica and therapeutics. How restricted this definition is, is well shown by a study of the examination papers in these branches, as printed in the catalogues of Harvard University, since the graded course in medicine was established. Of the 291 questions in materia medica, 288 relate solely to drugs. The exceptions deal with articles of food. There are 164 questions in therapeutics; 152 deal with drugs only. Of the twelve exceptions to the rule, six are on the use of cold, one includes cold baths among antipyretic drugs, four refer to diet, while one is hardly an exception, "Course of acute rheumatism if left to itself; how can you improve upon this?"

Thus the narrow definition is perpetuated, and the student is led to look upon drugs as the most important part of these branches of the art.

In its broad sense the materia medica includes everything which can cure or mitigate disease. The Greek word from which therapeutics is derived signifies to wait on, to heal. Treated in this larger way, materia medica would no longer be, what the instructor in this department in the Harvard Medical School says it now is, "a most dry and uninteresting subject, which offers almost no attractions, and is, for the most part, a mere matter of memory." [19] Giving its wider meaning to therapeutics, it would include private hygiene, as it ought to do. Hygiene is the mother of our art. Medicine, surgery, obstetrics, all the specialties into which these subjects have been subdivided, depend for their successful practice upon an observance of its laws. Why should it not be given the place it ought to hold, as the source of the most certain and most effective powers we have over disease?

In a recent publication, the instructor in materia medica and hygiene in the Harvard Medical School says: "The old-fashioned method of teaching materia medica and therapeutics is, or ought to be, a thing of the past. In the best Continental schools these subjects are taught in a manner quite unlike that to which we in this country have been accustomed. Their teachers are not necessarily men of large medical practice. Indeed, the best of them are not practitioners at all. Their time is engaged in the study of the action of drugs and other remedial agents, and this, with necessarily more or less of their application to disease, they teach to their students, leaving by far the greater part of the practical side to the different clinical teachers." [20]

There can be no question that the subjects of materia medica and therapeutics, even with their present limitations, have outgrown the capacity of any one teacher. So far as the physiological action of drugs is concerned, it is true that it is better taught by a man whose time is devoted to scientific work. It is a branch of physiology, and its results are as certain as those of any other branch of that science. But when the application of these laws is considered, we pass from the field of truth into the tangled paths of experience. It may be clearly proved that a drug will contract the blood-vessels of a frog; it is not so certain that it will have the same effect upon a sick man, or that, if it does, it may not hinder rather than help his recovery. It may be taught by the man of no practical experience that, in the forming stage of sthenic pneumonia, large doses of veratrum viride will remove the excess of blood in the diseased part, and by paralyzing the general vaso-motor system, bleed the patient into his own blood-vessels. He may add that when consolidation has taken place, "one grave danger is failure of power in the right side of the heart," and that "under these circumstances a cardiac depressant would immensely increase the danger." [21]

It requires the practical knowledge which comes from experience to teach that the first stage of pneumonia has generally passed before the patient is seen; that, even if the crepitant râle is heard, the deep parts of the lung may be solid; or that, if the case is seen in its forming period, and directions are given in accordance with this theory of treatment, consolidation may occur in a few hours, and the danger of the drug be "immensely increased." [22]

The clinical teacher deals with the question of drugs as applied to the cases that come under observation at the moment. He may not touch upon drugs which are fresh in the student's mind. His instruction must reflect his own opinions, which may differ from those of his colleagues. Great as is the advance which the art of medicine has made since clinical teaching has become so important a part of the course of study, high as is the character of this teaching in the Harvard Medical School, there is need, I think, in all schools, of a wise and experienced man to give instruction in therapeutics, and especially in the uses and limitations of drugs. He should be competent to weigh evidence, to sift the trustworthy from the unreliable, the safe from the dangerous. He should have attained the ability which Hippocrates commends when he says, "I look upon it as being a great part of the art to be able to judge properly of that which has been written." [23]

A CONSIDERATION OF THE PARÆSTHETIC NEUROSIS.[1]

BY JOSEPH COLLINS, M.D., NEW YORK,
Instructor of Nervous Diseases in the New York Post-Graduate Medical School; Neurologist to the Demilt Dispensary, etc.

SOME two years ago, while attending the meeting of the Southwest German Neurological Society at Baden-Baden, my attention was attracted to a paper read by Dr. Leopold Laquer, entitled, "A Special Form of Paræsthesia of the Extremities." I remembered that we had seen a number of such cases in the clinic at the Post-Graduate School, and determined on my return to make a study of them with a view to their classification.

[1] Read before the New York Neurological Society, June 6, 1893.

The paper which I present to you this evening is based on an analysis of forty-three cases in which the symptom-complex, hereafter described, was the only evidence of illness. I have endeavored to exclude from these statistics other cases of acro-neuroses, which, while they present some of the symptoms of the following cases, have other individual symptoms more pronounced, such, for instance, as ignipedites, waking palsy, and the like. Before entering into a discussion of the details of the form of paræsthesia to which I wish to call your attention, I should like in the first place to give the clinical history of a single case that shows a typical picture of this most distressing disorder.

Mrs. L., thirty-nine years old, is married and does house-work, including needle-work, washing and scrubbing. She was born in Germany, and has a good family history. The patient is a stout, strong, well-nourished-looking woman, and gives the following history: About five years ago she began to complain of "pins and needles" sensations in both hands, the right worse than the left. This continued, off and on, for two years. She was then taken with a severe flooding, and since that time the sensations have been very much more troublesome. As a rule, they come on in the following way: She may go to bed quite well, with an entire absence of any sensations in the hands, and about four o'clock next morning she is awakened with a dumb, sleeping sensation, as if electricity was passing through them, or, as she expresses it, "as if her hands had gone to sleep, only a hundred times worse." These sensations persist after she arises; and rubbing, using, moving or chafing the hands, as is often done to restore the circulation, gives no relief. The symptoms are somewhat ameliorated when she gets up and stands or walks about with the hands hanging by the sides. During the day, when she works about the house, the paræsthesiæ are not present; but when she stops and takes up sewing or sits quietly or lies down, and particularly on the following night, the sensations are very severe. In this patient the paræsthesiæ never occur in the feet. There are no objective symptoms. Her general health is good, appetite normal, bowels constipated, menstruation regular but excessive; she has headaches occasionally, and gets tired much more easily than formerly.

It will be seen that the clinical picture, in brief, is as follows: The sufferers from this affection are in fairly good health; that is, were it not for the paræsthesiæ, they would not have occasion to consult a physician. The paræsthesiæ which they complain of are made up of gnawing, boring, "pins and needles" sensations in the extremities, particularly the upper, and involving the fingers, hands and forearms, often of both sides, but not infrequently of only one. These sensations are not limited to the distribution of any one particular nerve in the extremity, but spread over entire segments of a member, such as a hand or forearm, with equal intensity. There is rarely any pain in the sense in which that word is ordinarily used. Using the word pain as the antithesis of pleasure, this paræthesia furnishes a form of exquisite pain. While the paræthesiæ lasts and in the interim between attacks, which is always a variable period, there are no fairly constant objective phenomena. Occasionally, the circulation of the extremities is evidently somewhat sluggish. There is absolutely no tenderness on pressure over any of the nerves of the part, and no perceptible changes of a trophic, motional or degenerative nature. The affection shows itself intermittently in paroxysms, and the period of the twenty-four hours when an attack is most likely to show itself is from four to six in the morning. The perverted sensations at this time become so severe as to awaken the patients and put an end to farther rest. Another favorite time is a corresponding hour in the afternoon. As a rule, however, the attacks in the day-time have a very close relationship to the work that the patient has been doing. In one subject to this form of paræsthesia an attack can almost always be precipitated by doing sewing or any other needle-work and by washing or scrubbing. There is no loss of sensibility to any form of sensorial irritation, nor is there loss of muscular strength on testing with the dynamometer. The patients complain, however, that the strength of their arms is more easily exhausted than formerly, and they cannot so easily sustain effort. In some cases the patients will describe other subjective sensations; but, in the main, they are as I have given them.

In studying the etiology of this affection, I find that the average age of the patients is just above thirty-nine years. Of the 43 cases on which this paper is based, 35 were women, eight were men. The age ranged from twenty-three to fifty-nine. Of the 43 cases, 26 were in the decade between thirty-five and forty-five years. Of the 35 women in the series, seven had suffered at some not very remote period either from metorrhagia or flooding.[2]

I want to emphasize this point somewhat, as it seems to have an indirect bearing in the etiology. Of the 43 cases, six had suffered previously from rheumatic or gouty pains, and of these three were males. In eight of the cases there was evidence of more or less anæmia. The most striking factor in the etiology, however, is the occupation. Of the 34 females, about 55 per cent. did either washing or scrubbing, crocheting or needle-work of some kind. Of the males, one was a waiter and dish-washer in a restaurant, another was a carpet-stretcher. Of the females, five were nursing children, two were pregnant. The time of the year in which the paræsthesiæ were most troublesome does not seem to be pertinent, and changes in the weather have no effect except that these patients naturally become, after a time, anything but cheerful, and inclement weather adds to their gloom. Neither heredity nor neuroses, such as hysteria, neurasthenia, etc., can be associated with this form of paræsthesia. Schultze has recently stated[3] that the sudden exposure from heat to cold has a causative influence, but I have been unable to find it in my cases, nor have I been able to induce the paræsthesia artificially in this manner, as will be spoken of later. Regarding disturbances of digestion being at the bottom of the trouble, as has been positively stated by Saunby, I must say that the digestive functions were carefully studied in many of the more recent cases of this series,

[2] Of 183 cases selected from the literature, including our own cases, the following etiological bearings are seen:

Number of females 151, males 32. Average age 40.7 years.

Number of cases between	15	and	25	. . .	.	19
" " "	25	"	35	. . .	.	43
" " "	35	"	45	. . .	.	58
" " "	45	"	55	. . .	.	37
" " "	55	"	65	. . .	.	23
	Over		65	. . .	.	2

Of the 151 females in which the occupation was noted, 39 did scrubbing and washing, 48 did needle-work, and 23 did house-work. In two cases only was direct heredity seen to be manifest.

[3] Deutsche Zeitsch. f. Nervenh., 3d Vol.

and rarely was any particular disturbance of it found. When alcohol is apparently a causative factor of the paræsthesia, it should, I believe, be classified under the toxic variety. What relation this form of paræsthesia bears to autotoxæmia and the lithæmic constitution is not so easily disposed of. Unquestionably, there exists in the minds of many physicians who have observed this neurosis some illy-defined ideas as to the relationship of lithæmia and this form of paræsthesia; but I gravely doubt if there be any closer relationship between it and the lithæmic diathesis, than there is between lithæmia and the development of neurasthenia or some of the vaso-motor neuroses. Lithæmia in itself is the result of deficient oxidation of proteid matters in the blood; and as the manifestations of this form of paræsthesia is through the peripheral blood-vessels it is extremely plausible that the paræsthesia is not the result of the lithæmia but one of the factors on which the lithæmia itself is dependent. We are forced to this conclusion by the results of medication directed to the lithæmic state alone, which is very unsatisfactory. The other hæmatotoxic conditions of gout and rheumatism do not seem to have any causative relationship. Bodily fatigue, over-exertion, poor nourishment and ventilation, lactation and in fact anything that lowers the vigor and health of the body, are powerful predisposing factors. The hands are the parts affected most frequently. In 43 cases both hands were affected alone in more than 50 per cent. of the cases; all four extremities in nine cases, and one extremity in ten cases. When the paræsthesiæ came in one extremity at a time, I do not mean to say that this one part was solely the one affected. The following case illustrates how the sensations would leave one hand and go to the other.

Mrs. A., forty-one years old, American, married, and does house-work. Personal and family history good. She has never had a severe sickness except uterine inflammation and metrorrhagia after a miscarriage. For the past four years she has been troubled with boring, heavy, "pins and needles" sensations in the hands, and less in the forearms. She never had the sensation in both hands at the same time, but frequently when it passes away from one hand it appears in the other. She noticed this trouble for the first time shortly after the miscarriage already mentioned. These tingling and dumb, sleeping sensations in her hand awaken her early in the morning, and rubbing, squeezing and using her hands does not seem to dissipate the sensations. The greatest relief is obtained by wrapping her hands in flannel and applying dry heat. The paræsthesiæ are slightly more troublesome in wet weather; it never affects the lower extremities. If she washes to-day the painful sensations to-morrow would be almost unbearable. She suffers considerably from headache. Before concluding what I have to say about the etiology of this form of paræsthesia, I wish to refer again to the possibility that metorrhagia has more than a casual relationship in precipitating this affection and in helping to keep it up after it occurs. Of the 34 women in this series of cases no fewer than 12 gave a history of flooding at some time, before or during the tenancy of the paræsthesiæ. I do not wish to be quoted as saying that flooding is the cause of this paræsthesia, but that it sometimes appears to be an etiological factor. The menopause I do not find to stand in close relationship although the preponderance of cases is between thirty-five and forty-five years. These patients are not necessarily at the change of life, and as a matter of fact most of them are not.

One of the most aggravating cases that we have had to treat at the clinic was that of a lady sixty years old who gave a typical history corresponding to the one above, except that the paræsthesiæ affected all the extremities. This patient, notwithstanding her age, was menstruating regularly. Two cases (women) gave a history of excessive sexual intercourse, but with "withdrawal" on the part of their husbands. This had been practised for some years to avoid conception. It is admitted by gynæcologists that indulgence in this practice is followed by a condition resembling sub-involution and metrorrhagia as a natural sequence.

Taking these etiological factors into consideration, one is led to the question as to what the probable seat of the trouble may be. Nearly every one who has written on paræsthesiæ has had something to say on this point, in which he differed from others. It seems to me that we can exclude any trouble in the central nervous system and spinal cord. It is scarcely necessary for me to enter into details for the basis of this statement.

I am of the opinion that this form of paræsthesiæ is due to defective innervation in the blood-vessels which causes a low degree of blood-pressure and lack of proper blood-supply to the terminal branches of the peripheral sensorial nerves. That is, the vascular changes may be secondary to central exhaustion. The perception of paræsthesiæ is, of course, a central process. It is probable that frequently in the beginning this paræsthesia is set up in a predisposed neurotic subject, and as a result of the combined influence of central cortical over-stimulation (from the reception of the peripheral impressions) and the suffering of the patient, acts upon ganglionic cells in certain areas of the cortex and produces exhaustion. This may be called a functional exhaustion similar to that produced and observed by Hodge. The causative factors of this form of paræsthesia are extremely chronic and remedial measures when not associated with rest are rarely beneficial. While rest, mental and bodily, is frequently followed by great relief I am therefore inclined to agree with Laquer that it may be an exhaustion neurosis.

On a few of these patients I instituted some experiments for the purpose of corroborating the opinion that vascular changes may start anew the paræsthesiæ. If the patient, whose history I have detailed at the beginning of this paper, was made to hold both hands above the head the paræsthesiæ would set in with such intolerable severity after four minutes that she could not keep them in this position. If one hand was held above the head and the other by the side the paræsthesiæ would come on in the uplifted hand while the other hand would remain free. Putnam has noticed a similar condition in some of his patients. After the hands had been elevated for a few minutes and the paræsthesiæ had appeared and they were then allowed to hang down they could be seen to become dusky in color and swollen-like, showing that there was more or less vascular congestion following a transient anæmia.

Another patient who had paræsthesiæ in the hands alone, had her hands dipped in water of the ordinary temperature, and allowed to remain there for from five to ten minutes, with no resulting paræsthesiæ. But if the hands were first dipped in very hot water

and then in iced water the tingling sensations would come on after a few minutes. If the order was reversed, that is putting one hand in the cold water first and the hot water afterwards, the paræsthesiæ did not seem to occur.

Another patient, a male, shoemaker, who suffered from paræsthesiæ in all four extremities, was experimented on with Fleming's Tincture of Aconite, a drug which in small doses is known to lower blood-pressure and produce a lessened amount of blood, particularly to the periphery of the body with a high degree of certainty. One drop of this tincture was given every fifteen minutes to this patient when he was free from the paræsthesiæ, and almost invariably every time he was subjected to this treatment, by the time he had received the fourth dose the paræthesiæ would occur.

It was not, I believe, the tingling which is caused by the absorption of a considerable amount of aconite into the system for two reasons: first, the tingling that results from large doses of aconite occurs in all parts of the body in the order of their sensitiveness as determined by Weber; and secondly, because in the same patient, veratrum viride, a drug which does not produce tingling, was followed in its administration by similar results to those obtained by aconite. Such experiments are in no way conclusive, but they are suggestive as to the probable conditions antecedent to the development of the paræsthesiæ. The fact that the hour out of the twenty-four when these sensations come on with considerable certainty is in the early morning, a time when the ebb of life is at its lowest tide and the blood-pressure registering nearest the base line, is another bit of evidence in favor of the idea that the essential preceding condition in the development of the paræsthesiæ is a vascular one. That it occurs when the patient lies down as, for instance, in the day-time, and after use of the parts, as in working, scrubbing or needle-work, etc., is not inconsistent with this line of thought.

I cannot agree with some writers on the subject who say "we shall not have to look far for a solution of this difficulty. It is evident that we have faulty or imperfect actions in some of the more important tissues or structures of the ecomomy, such as degenerative changes in the vessels, etc." From a rather careful study of the vascular system in these patients with the aid of the sphygnograph I must say that it is but rarely that I have found any indications of arterial degeneration.

Before saying a word in regard to the treatment which has been found most successful with these patients I would like to suggest a classification of the paræsthesic neurosis, and illustrate each of the divisions by citing a typical case. Of course, it will be understood that I rigidly exclude the neuralgias, neuritis, ignipedites, etc. The following classification is principally on an etiological basis:

(1) Emotional.
(2) Mental.
(3) Neurasthenic.
(4) Toxic.
(5) Waking numbness.
(6) The one under consideration which may be called an occupation paræsthesiæ, so often is it associated with a certain class of occupations.

As an example of the first form, I cannot do better than to present the notes of a case reported by Dr. Dana. A gentleman forty years old, a cotton-broker, suffered from almost constant sensations of numbness, prickling, etc., of the left arm and hand, extending up to the elbow. The symptoms annoyed him to the last degree. There was no anæsthesia or objective changes in the hand, and the patient was in good general health. He was an excessive smoker, but interdicting this and subjecting him to various forms of treatment was followed by no benefit. Finally, after some months cotton went up and the affection gradually left him.

As a type of the paræsthesiæ depending upon a disordered mental state the following case of galeanthropy or *Katzensucht*, as it is termed by the Germans, may be related. A young woman twenty-seven years old, who had inherited marked neurotic taint, her mother having died of cerebral softening at forty years old, one aunt of insanity at thirty-three years old, and one great-aunt had epilepsy. The patient herself was always very nervous when a child. For a considerable time she had complained of inability to sleep well, and in the morning of most distressing sensations; tingling, numb, pinching sensations in the hands and forearms, particularly the right, and in the feet worse than in the hands. These sensations persisted most of the day, but disappeared toward evening. In addition to the paræsthesiæ of the extremities she says there is an area about as large as the hand above her right buttock where the sensations also appear. After suffering from these paræsthesiæ for some time she had a transient attack of the mania known as galeanthropy. The attack come on in the following way: After some very trying domestic infelicities she was left alone one day, and was sitting brewing her troubles, when she noticed that a picture of the "Father of his Country," hanging on the wall on the opposite side of the room, suddenly began to misbehave in a most remarkable manner. Then all the other pictures on the walls followed this illustrious example. This kept up for some time; and then she thought she was being transformed into a cat; and after that she acted like a cat, walked on all fours, spit and scratched when any one came near her, would not let them undress her or put her to bed, would eat only off the floor, tried to scramble up the bed-post and sides of the room like a cat, etc. She imagined she was consorting with other felines, and, in fact, gave quite a typical history of this form of alienation. After quite a protracted treatment this patient recovered from her mental affection, though she still has the paræsthesiæ occasionally.

The neurasthenic form is really quite common, and it is unnecessary to quote a very elaborate history. The following case seen in private practice may be taken as an example:

X., a married lady of forty-four years, was bred a lady of leisure, but circumstances at present compel her to manœuvre with a small amount of money invested in a business in order to make a living. As a result, she has developed quite a typical neurasthenic condition of the cerebral type. She has head-pressure and sensations, morbid fears and dread, loss of strength and ambition, and, added to this, paræsthesiæ of the hands and feet, which are extremely distressing. When the neurasthenic symptoms have their good days, the paræthesiæ are forgotten, and the reverse.

The toxic forms of paræsthesiæ, of which we see so many examples, are, I believe, mostly the indications of beginning multiple neuritis. Frequently, however, they do not go to extensive changes in the nerves and

muscles, and we see the manifestations of toxicity only in the paræsthesiæ. Many writers have spoken of this form of paræsthesiæ, and it is not infrequently associated with malarial poisoning, moderate alcoholism, and the ingestion of other poisons. In the following case it resulted from excessive tea-drinking:

C. B., female, fifty years old, native of England, married. Has had nine children. Has always drank a glass or two of beer a day, but drinks mostly tea, which is taken strong and often. She thinks seven or eight cups a day would be a low average. She says she keeps the tea on all the time, and frequently takes it in place of food. She reached the menopause about three years ago. For upwards of two years she has complained of burning, gnawing, prickling sensations in the feet and legs. Sometimes these sensations are really very painful. More recently she has felt similar sensations in the arms from the elbows down, and in the face. All around her mouth she gets prickling "pins and needles" sensations; and her face gets a sort of numb, wooden feeling in it, so that she has to put up her hand to feel if her face is really there. The appetite is fairly good, bowels constipated, and she suffers considerably from frontal headache and gets low spirited often. This patient, when tea and beer were entirely forbidden her, and she was put upon a nutritious diet with nux vomica and out-door exercise, improved steadily, so that now she is practically well.

Several other cases could be cited where the paræsthesiæ have disappeared after a prolonged treatment with anti-malarials.

Under the title of "Waking Numbness," Dr. A. H. Smith has described four cases of a condition which would seem to be a form of paræsthesiæ, to which is added more or less complete temporary abolition of motility. In a case presenting himself at the clinic, a barber thirty years old, of strong neuropathic predisposition, complained that when arising in the morning his hands were powerless, feeling as if he "had bowled tenpins too long the night before and had no strength in them," and with this, tingling, numb sensations. He had been in the habit of taking a nap during the slack hours in the afternoon, but he was obliged to forego indulging himself in this direction, as the numb feelings were sure to come on after awakening. This man improved under the use of galvanism, tonics, invigorating baths and out-door exercise, but he was lost sight of before he was completely well.

Then there are the paræsthesiæ that come with rheumatism, gout, arthritis, etc.; but they should be included under the division of toxic paræsthesiæ. We have had many good examples of the paræsthesiæ resulting from a combination of rheumatism, bad nutrition and depravity. One young lady, a dancer in a well-known ballet extravanganza, complained of a condition very much resembling the history just detailed. She had less periodical and more continual impairment of strength than did the last patient. She was very anæmic, run down, badly nourished, kept late hours, used enormous amounts of cosmetics containing lead, and had previously suffered from rheumatism. Her improvement was very slow, on account of the fact that necessity compelled her to keep on with her occupation and the harmful prerequisites which were incident to her business.

These illustrative cases of paræsthesiæ have been detailed for the purpose of showing that the paræsthesic neurosis presents itself under several different forms; and, with some license, they can be grouped as I have indicated. Recently, Schultze, of Bonn, has published an article dealing with the form of paræsthesiæ that I have considered in the first part of this paper. He has given to it the title of "Acro-paræsthesiæ." If I am right in my contention for the above classification, this term is not sufficiently definite to warrant admitting it to our nomenclature. Acro-paræsthesiæ simply means paræsthesiæ of the extremities. You will admit that the forms of paræsthesiæ that I have mentioned are of real occurrence, and could probably duplicate the cases I have detailed by a large number of cases.

Regarding the therapeutics of this special form of paræsthesiæ I can only admit and concur in what all previous writers have stated, namely, that we have no specific remedy. In my experience, prolonged rest has been the most important beneficial agent, particularly when restorative treatment is added.

I consider the administration of neurotics and depressants, such as antipyrin, phenacetin and the like, positively harmful. I have not found it necessary to treat specially and individually the digestive tract, for, as has before been stated, it is not customary to find it seriously at fault. Too much emphasis cannot be laid upon the point that everything which tends to exhaust these patients or in any way interfere with their vitality should be controverted. The use of the faradic current, in the shape of the faradic local bath, as recommended by Laquer, seemed to be very beneficial in two cases that have been under continuous treatment during the past winter. In fact, I may say that one of these patients has apparently recovered under this treatment after she had acted upon the advice to wean her baby, which she had been nursing for a long time. The galvanic current has not given anything more than temporary relief. So far as treatment has been given with directness to combat any lithæmic diseases that have been supposed to exist, I must say candidly that I have seen no startling results. Some of these patients have been on spring water and mineral acids without any beneficial results.

The plan of treatment which is most beneficial is regulation of the diet (particularly by limitation of the nitrogenous food-stuffs), quiet out-door life, change of occupations and habits, and the administration of restoratives.

APPENDICITIS FROM THE POINT OF VIEW OF THE PHYSICIAN.[1]

BY GUSTAVUS ELIOT, A.M., M.D., NEW HAVEN, CONN.

Recent years have witnessed great advances in our knowledge of inflammatory affections in the neighborhood of the cæcum. The vermiform appendix now occupies a position of great pathological interest and importance. The proper management of inflammation of this organ is a subject in regard to which eminent authorities still hold very dissimilar opinions. Every practitioner is likely at any time — it may be to-morrow, or next week, or next year — to meet a case of appendicitis, and to be confronted with the question: What does modern science teach should be done for the patient?

The responsibility of the practitioner in these cases can scarcely be overestimated, because the danger of a fatal result is so great, and because the life of the patient so often depends upon his decision. The intrinsic tendency to recovery is slight.

In post-mortem examinations it is possible to distinguish cases in which the disease is plainly due to the presence of a foreign body, and those in which it is impossible to find any such cause. Cases in which the inflammation is not dependent upon a foreign body, and which are distinguished as catarrhal, are the ones in which the symptoms sometimes subside in two or three days. Frequently, however, by the death of tissue, they become closely allied, as regards their ultimate results, to cases of the first class, for the dead tissue is practically a foreign body.

The results of appendicitis are various. Sometimes the inflammation quickly undergoes resolution, the symptoms subside, and the patient gets well without appreciating the danger through which he has passed. In other cases the peritoneal cavity early becomes infected, and general peritonitis and, as a rule, death quickly supervene. In still other cases a chronic abscess forms. This may burst and cause general peritonitis and death; or it may undergo spontaneous evacuation and result in death or recovery; or it may be opened by the surgeon, and terminate in death or recovery.

From an etiological, as well as from a pathological point of view it is therefore easy to see that the patient with appendicitis has many chances of his disease terminating fatally. It is the obvious duty of the physician to remove his patient as far as possible from the chances of a fatal result.

Before pus has formed, before ulceration has perforated the coats of the appendix, and before the appendix has become gangrenous and sloughed, the danger to the patient is a prospective one. During this stage of the malady, the physician must adopt a course of active medical treatment. Morphine should be administered in large doses subcutaneously, and should be repeated at short intervals until the pain is entirely relieved. A mustard plaster should be applied until the skin is reddened, and this should be followed by hot flaxseed poultices. A saline cathartic — sulphate of magnesia, in drachm doses, is the best — should be repeated every hour or two, until copious watery movements from the bowels occur. These measures tend to relieve the congestion of the intestinal mucous membrane, and to modify the inflammatory action. If the case is one of so-called catarrhal appendicitis, in which there is no foreign body and no abnormal concretion giving rise to the inflammatory process, the inflammation may undergo speedy resolution and the patient quickly become convalescent. But, on the other hand, resolution may not ensue, and the patient may not get well.

If, however, the trouble is caused by a foreign body, or an intestinal concretion, the measures above indicated will do very little good, except to keep the patient quiet, while the doctor is thinking what to do next.

Cases of this kind, and cases of catarrhal appendicitis, which have not undergone resolution, may be classed together. They are of great gravity and importance. Unfortunately, during the first stage of the disease it is generally impossible to tell just what the cause of the trouble is. It is, therefore, playing a game in which the odds are strongly against both the patient and the physician, to continue indefinitely the treatment which I have outlined. The most important point is to decide how long this treatment may be safely continued.

Statistics will in time doubtless settle the question with reasonable certainty. They have not done so yet. It is, however, known that, in many cases, the dangerous results, suppuration, sloughing and perforation occur very quickly, sometimes as early as the third or fourth day. The risks of temporizing with a suppurating, gangrenous or perforated appendix are so great that no man who has any conscience ought to hesitate for a moment to advise its removal. The sun has nearly set upon the day in which the surgeon boasts with pride, as of an important operation, of having incised a large perityphlitic abscess. The day will soon dawn — it has already dawned for some — on which such a performance will be mentioned only to illustrate the carelessness, the stupidity or the mistake of the man who watched the abscess develop.

The question then is: When shall the diseased appendix be removed? It has been the fashion for the surgeon to say: You must call upon me to tell you when the operation should be done. This is pernicious teaching. It is time that the physician should turn about, and say to the surgeon: when I want you, I will send for you. When I send for you, bring your ether cone and your knife.

As I have said statistics have not yet told us just when to operate. But the daily newspapers have told, to him who reads between the lines, that the patients die when the operation is delayed. It is certain that the fourth day of the disease is, in some cases, too late to operate and save the patient's life. There is very little satisfaction in operating and then seeing the patient die. The third day is, to many of these cases, a critical one.

To return to the former question: How long may medical treatment be continued? My reply is for not more than twenty-four hours, and not later than forty-eight hours, from the commencement of the disease, unless distinct evidence of positive and continuous improvement is observed. If it is not observed, call upon a surgeon to operate, and call upon one who will operate. In this way alone will you do your duty by your patient.

I doubt not that some one, who desires to pose ostentatiously as a conservative, will jump up, when I sit down, and tell you that I am young and inexperienced. Concerning these points I have nothing to say.

[1] Read before the Connecticut Medical Society, at the one hundred and first annual meeting, at Hartford, Conn., May 25, 1893.

What I wish to impress upon you is that the experience of the profession during the last few years teaches that an inflamed appendix should be removed after forty-eight hours, if marked evidences of resolution of the inflammation have not appeared by that time. To be sure all patients, who are not operated upon, will not die; but many will die, if the operation is postponed much later than the period mentioned. If you think that I am wrong, tell me: Have you ever heard of any one who removed an inflamed appendix, who was sorry because he had not postponed the operation until a later day? You know that many fathers and mothers have wept bitterly over the loss of a loved child, who died because the surgeon did not operate until the disease had passed beyond the range of his resources.

Now, my dear brother physician, do not try to shirk your own individual duty and responsibility, by calling in a surgeon and throwing the responsibility upon him; and, if he sacrifices the patient's life, do not sit stroking your beard with a look of sanctimonious resignation upon your face, while you explain that the eminent authority, who was called in consultation, advised postponing the operation, or against operating at all. Call a man who will operate at once, and who will operate well, and call him early before the case gets complicated.

Do I hear some one say that the operation increases the danger of the patient's dying? Let me ask again: How many of you have heard of any patients who have died from the disease or the operation, when the appendix was removed before suppuration, gangrene or perforation had occurred? I am sure that such cases are exceptional. I advise you to adopt a course which brings safety to your patient, which removes him from very great danger to his life, or at least from a prolonged and dangerous illness, by a surgical procedure, which increases very little his liability to death.

This is genuine conservative surgery. I speak not as a surgeon who is anxions to use his knife at every possible opportunity, but as a physician who recognizes the duty of deciding what is best for his patient, and of making every effort to have the right thing done at the right time.

One suggestion has been made in this connection which is deserving of respectful consideration. Some have advised that temporizing measures should be employed, in the hope that the acute symptoms may subside, and that, after they have disappeared, the operation should be performed. The danger of the operation is less, they claim, after active inflammation has passed away, than while it is still present.

There are several objections to following this plan. In the first place it is very questionable if it is wise to operate upon a patient after his first attack, if all symptoms of the trouble have passed away, for it is well recognized that many persons suffer from a single attack, and have no recurrence. Although the danger from the operation is not very great, yet it is sufficiently great to lead us to advise any one, with considerable hesitation, to submit to the operation, when he is in apparently good health. A better plan is, after the patient has recovered from the primary attack, to warn him of the danger of a subsequent attack, and, if the second attack ever occurs, to advise immediate early operation.

Another objection to the plan of waiting for the subsidence of the acute symptoms is that it is impossible to distinguish cases of catarrhal appendicitis, which may undergo resolution, from cases due to the presence of a foreign body, which rarely undergo resolution. Most cases of the latter variety, and many of the former, do not undergo resolution, but speedily getting worse, pass beyond the first stage, and become complicated by suppuration, perforation or gangrene. These complications are very serious. They increase very greatly the difficulty and danger of operation, and very often render a fatal result inevitable.

For these reasons there seems no occasion to question the wisdom of the rule already laid down: That the appendix should be removed within forty-eight hours of the commencement of inflammation of the organ, unless marked improvement is observed after twenty-four hours of medical treatment.

The risk of a fatal result being hastened by an operation, carefully performed, while the case is still uncomplicated, is very slight compared with the increased danger of death if the operation is delayed until an abscess has formed, or the tissues have sloughed, or ulceration has resulted in perforation.

Clinical Department.

A CASE OF PREGNANCY COMPLICATED BY PNEUMONIA AND EMPYEMA.

BY GEORGE A. CRAIGIN, M.D.

I HAVE ventured to record the following case because it is rather unusual; few are reported; and a number of practical questions are suggested.

The patient was a married woman, thirty-four years old. She was small of stature, but well developed and nourished. She had had three children; all now living and well. Her previous history was excellent; no illness of any account.

The early part of the present trouble is a little obscure. About the middle of December, 1891, she was taken suddenly ill with high fever and severe pulmonary symptoms, suggestive of *la grippe* with pneumonia. She had been ill nearly a week when I saw her on December 24th.

I found her sitting up in bed, in great distress; the eyes suffused; the face flushed a dull red; moderate cyanosis. Respirations shallow, 48 per minute, the movement most marked at the left apex; the pulse 140, regular, full, of fair strength; temperature 103.4° F.

The condition of the lung on the right side was doubtful. The respiratory movement was imperfect; the resonance fair; respiratory murmur faint, having in the lower half very little vesicular quality, and obscured by numerous sticky râles (possibly a resolving pneumonia). On the left side the resonance was fair in the upper two-thirds; dull at the base, front and back. The respiratory sounds were normal at the apex, faint at the base, with diminished voice — apparently due to a moderate pleural effusion. The abdomen was somewhat enlarged by the pregnant uterus at five to six months.

The patient's chief complaint was of great distress for breath and a constant harassing cough, so that she could not sleep and could scarcely speak. The severe dyspnœa was at first controlled very satisfactorily by

[1] Read before the Boston Society for Medical Observation, April 3, 1893.

nitroglycerine (gr. $\frac{1}{100}$) every four hours; but in a few days the effect wore off.

During the first forty-eight hours the temperature fell by crisis, the pulse going with it; but the respirations remained high. The fall of temperature and pulse was probably due to the crisis of a pneumonic process; but a reason for the sustained high rate of respiration was found in a steadily increasing effusion in the left pleural cavity. By the 29th of December, the twelfth day of the disease, this had reached the third rib in front, and the heart's apex had been pushed under the sternum.

The condition of the right lung remained unchanged, apparently useful only at the apex. The left chest was aspirated in the seventh space, below the angle of the scapula; and forty-five ounces of sero-pus withdrawn (on standing one-eighth pus).

The operation gave a little relief to the distressed breathing; but cough became exceedingly troublesome, the sputum thin and frothy (perhaps from œdema). Repeated doses of morphia (gr. $\frac{1}{4}$), with atropia (gr. $\frac{1}{100}$), gave only short naps. She had to sit up all the time. Yet strength and general condition seemed good.

The temperature, which fell to normal on the morning of the aspiration, never rose again above 100° F. The pulse remained over 110, often 120, during the following week; and the respirations ran between 45 and 60, as a rule. The symptoms remained much the same, though dyspnœa and cyanosis became more marked as the effusion increased.

By January 8th the left chest was again filled to the third rib. Forty ounces of pus were aspirated at the same place as before. That night severe stabbing pains on respiration were felt in the right side, and retraction of the lower intercostal spaces during inspiration was noted. The physical signs on this side remained the same.

In spite of everything, the patient's strength held out well, and she was able to walk about the room when her bed was being aired and made up.

At the end of ten days (January 19th) the chest was full as before; but during this time the patient had grown steadily worse. Dyspnœa was severe, the respirations during the last week scarcely ever falling below 60 day or night. Sleep was almost impossible. There was constant epigastric distress, much worse after the lightest meal of milk or broth; so that very little nourishment was taken. Cyanosis grew marked — the face gray and anxious. The pulse fell some in rate, but became irregular. The sputum was considerable — thick, muco-purulent. The general strength was failing noticeably. She was now over six months pregnant, and fœtal movements were distinctly felt.

It was evident that further aspiration would be useless, and that free drainage should be secured at once, to relieve the embarrassed lungs and heart. Dr. Prescott kindly saw the patient with me and agreed about the operation.

Primary anæsthesia was used. There was very little shock. Within twelve minutes of starting the ether the bandage was on, and the patient perfectly conscious. A good-sized double rubber drainage-tube was put through an one-and-a-half-inch incision in the seventh space, axillary line. There was a large amount of thick pus.

There was a return of the severe pain in the right side, as after the second aspiration, and the cough became very troublesome.

Five days after this the note says: "Has been considerably relieved by the operation. Epigastric distress nearly gone; appetite a little better; face not as anxious; color improved. The cough has been very hard, and has not yielded to morphia (gr. $\frac{1}{8}$) or codeia (gr. $\frac{1}{4}$) every two hours (by mouth)."

So violent, in fact, was the cough that air was forced into the loose tissue about the wound, and soon there was a general emphysema from the zygoma over cheek, neck, shoulder, back and side to the buttocks. The rubber shield holding the drainage-tube was lifted from the chest wall with rolls of gauze. As soon as the wound surface had granulated well, the air ceased entering, and the emphysema gradually disappeared without having caused any real discomfort. The tubes were shortened occasionally, and drainage was very good. Irrigation was not practised.

After the operation the temperature scarcely ever rose to normal, running between 97° and 98° F. The pulse, however, for ten days remained pretty constantly at 120, morning and night; was rather soft, fairly regular, and not influenced by digitalis or strophanthus. The respirations also remained rapid as ever, being 50 or 60 all the time.

The appetite was poor, and there began to be considerable epigastric distress again about January 30th. Up to this time, although failure in strength had been steady, it was not as rapid as before the operation; and there had been a decided increase in comfort. The fœtal movements were strong.

The note on February 2d says: "Appetite failing. Expression anxious. Gradual emaciation. Sweating. Pain in left side, front and back, and in wound, increased by a troublesome cough, which is aggravated on lying down. Sputum abundant — thick, muco-purulent. Examination showed the apices fairly clear — the right base same as usual, the heart in nearly normal position. Drainage free. Considerable purulent discharge."

During the greater part of February the pulse and respiration remained almost unchanged. For more than eight weeks the pulse had averaged over 110 in the morning, and the respiration over 50. Patient's general condition varied from time to time. Profuse sweats were not infrequent, with great exhaustion; and she about gave up hope of recovering or even living to have a full-term child.

But toward the end of February and in March there was improvement. The pulse gradually came down, grew steadier and stronger; the respirations, by the middle of March, had dropped to 30; the appetite came back; the face had better color; the expression was brighter; and the cough and pain were much diminished. The discharge had decreased, till on March 12th the notes show an average of about two drachms in twenty-four hours, and the descent of the lung made it difficult to retain the drainage-tube. The sweating was considerable at times. Judging from the fœtal movements, the child was strong.

An examination of the sputum by Dr. Greene showed numerous tubercle bacilli.

The physical signs in the right lung remained as before — clearer above than below, where numerous sticky râles obscured everything. There was some retraction of the intercostal spaces still. On the left side there was a gradual increase of vesicular quality, and in neither apex any definite sign of consolidation.

The course of things was uneventful till March 26th

when after an easy labor she gave birth to a strong, good-sized child, presumably full-term.

The tube was removed April 11th.

On May 11th there was still a little discharge. At this time the right lung seemed clear, and the left sound to the fourth space axillary, lower in back. The patient was now up and doing light work, with only a little cough.

During the summer she was sent off into the country, and improved rapidly. The child was breast-fed from the beginning.

I have seen her again quite recently. Appetite, strength and flesh are good as ever. There is occasional pain independent of respiration, both in the left chest (through the præcardium to the back), and in the upper part of the right chest. There is occasional dry cough. The expansion is rather deficient on the left side, though still fair. Fremitus present, but relatively diminished. Vesicular respiration is heard to a point an inch below the wound, front and back, though fainter than above, and relatively less than on the right side. The voice sounds correspond. The percussion note is duller than on the right, but there is resonance below the wound, corresponding to the respiratory murmur. There is no trouble at the scar. Respirations are 18–20, full and free; pulse 82; the heart in the normal position. The child is living and well though rather delicate looking.

Comparing this case with the reports and statistics of others, there are a number of points worthy of notice. Opinions concerning the relations of pneumonia, pleuritic disease and pulmonary tuberculosis to pregnancy are much at variance; and consequently the matter of treatment in certain important points is also undetermined.

Pneumonia in pregnant women does not appear to be more or less frequent than in women of the same age and social state who are not pregnant. It is important, however, to know whether pregnancy has an appreciable effect on the acute disease. This would be difficult to determine unless the effects were very marked and constant, there being so great a variation in degree, according to the particular season, the treatment, and the constitution, habits, and previous history of the patient.

In the case reported, the pneumonia (if it were such) appears to have run a natural course, the temperature dropping by crisis on the eighth day. A number of observers, however, consider that the onset is liable to be more severe and the fever higher in pregnancy; and others that the farther advanced in pregnancy the greater is the extent of lung involved, and, therefore, dyspnœa, etc.

The effect of pneumonia on pregnancy should be more easily determined.

In our case the effect was *nil;* but it should be noted that the attack came on in the sixth month. While there is contradiction between the figures of the early and more recent observers, the general opinion now is that the later the disease in pregnancy, the greater the liability to disturbance or interruption of pregnancy. Thus, out of a series of 17 cases, 10 had pneumonia before the seventh month, and but three aborted; while of six which had pneumonia after this period and before term, four miscarried. (The other cases were taken ill at term.)

There have been numerous attempts to explain the cause of interruption of pregnancy in pneumonia, and the assigned causes are almost as numerous. Among these may be mentioned hyperpyrexia, hydræmia, uterine contractions stimulated by imperfectly oxygenated blood or severe coughing, and death of the child from various causes. Death of the child *in utero* is ascribed to hyperpyrexia, want of oxygen, hydræmia of mother, catarrhal pneumonia of child from inhalation due to asphyxia, insufficient supply of sodium chloride in maternal blood, and (in the light of recent investigations) acute infection by the pneumococcus through the placental circulation.

The prognosis for the child is poor, even when it is born alive, after being carried to term. Thus Wells reports eleven cases of his own where the pneumonia occurred in four during the first three months, and later in the other cases, with three miscarriages, and one induced labor. All the children were born alive; yet but one lived for any length of time after birth.

The prognosis for the mother appears from statistics to be decidedly worse when pregnancy has been interrupted, the danger increasing with the advance of pregnancy. Some tables give a mortality as high as 17 out of 19; one gives 71 out of 104; others lower. Cause and effect are liable to be confused here in drawing inferences from figures, as it is probable that the pneumonia itself was of a much severer type in most of the cases where pregnancy was interrupted.

The prompt fall of the temperature in the case just reported soon relieved me of considerable anxiety, but there was time enough given to suggest a number of questions which might demand an answer in a less favorable case:

(1) Does the distended abdomen of pregnancy diminish the air space in the thorax to any extent, so that emptying the uterus would relieve dyspnœa?

(2) With continued high temperature and increasing dyspnœa and cardiac weakness, would induced labor be advisable? or, if miscarriage is threatened, should every effort be made to stop it?

(3) In case the child were viable, but showed signs of failing strength, would induction of labor be justifiable whether the mother's condition were favorable or not?

It is evident from my case, that, in spite of the pneumococcus, moderately high fever, great dyspnœa and racking cough, pregnancy at five to six months may continue smoothly without any appreciable effect on the child.

Pleurisy complicating pneumonia is very frequent; and pleurisy with effusion not rare, even in an early stage; but empyema is rare.

Verneuil has said that the pregnant woman has a distinct tendency toward pus formation. If this is so, the case reported is one in point. As a considerable proportion of the fluid drawn at the first aspiration was pus, it is evident the effusion was purulent at an early date. It was noticeable that neither aspiration was followed by the relief which might have been expected from the withdrawal of so much fluid. It is probable, however, that the distress and danger would have rapidly increased had the effusion been allowed to accumulate further. The permanent drainage itself seemed rather to hold things in check than to give very definite relief.

As to the propriety of aspirating or draining whenever there are the usual indications independent of pregnancy, it seems to me there can be little question. Anæsthetics are given and operations performed so

frequently during pregnancy without deleterious effect, that little is to be apprehended. Shock and severe pain are probably the most to be feared. Particular attention would naturally be given to the usual precaution against emptying the pleural cavity too rapidly or too thoroughly. As to giving an anæsthetic there may be difference of opinion. Profound anæsthesia when there is any embarrassment to breathing or circulation is undoubtedly dangerous; and in a pregnant woman the subsequent nausea and retching might increase the danger of miscarriage; but the rapid primary anæsthesia, which is all that should be required for the drainage operation (unless resection of the ribs were done), has little danger; and that is overbalanced by saving the patient from the pain and fright of a cutting operation. Moreover, the operator can be much more deliberate and will run less danger of cutting intercostal vessels or wounding the diaphragm.

The persistence, for eight weeks, or more, of respirations over 50 and of pulse at 120 on the average is remarkable; but even more so is the fact that pregnancy should have progressed so evenly in spite of marked cyanosis, distressing dyspnœa, vomiting, and a cough so frequent and violent, together with progressive failure of strength, loss of flesh, sweating, etc.

When these became marked and the sputum was found to contain tubercle bacilli the outlook was grave. The question arose whether it might not be better, for mother and child, to induce labor, as there seemed a possibility of her failing so rapidly that both might die.

If it were established what influence pregnancy, abortion, miscarriage and labor have on the course of pulmonary tuberculosis, it would be easy to determine a line of treatment in such cases; but, strange to say, opinions are far from unanimous in this comparatively familiar field.

It is important to know, whether tuberculous patients become pregnant less often than others; whether pregnant women are more or less liable to tuberculosis; whether pregnancy hastens or retards the tubercular disease; whether the course is more precipitate after confinement, or induced, or premature labor.

Evidently these questions can best be settled by the experience of men with large private practice rather than by hospital statistics, where little is known of previous and subsequent history.

CANNABIS INDICA.

BY ROBERT T. EDES, M.D.

Extract of cannabis indica is one of those drugs which always possess a great fascination for the incipient experimental pharmacologist (very frequently a medical student); and yet there is perhaps even less to be said as to its mode of action than of its immensely more powerful congener, opium.

It is strange that with such strongly marked and highly characteristic subjective symptoms, recognized by every one who has experimented upon himself with it, that is, the immense apparent prolongation of space and time; and the double consciousness, so interesting in its possible relations to hypnotism, that this drug has awakened so little attention on the part of the modern school of experimental psychology.

It has, however, notwithstanding the interest attaching to it, never attained an important position as a hypnotic; probably for two reasons, the first and most important being that it is far from being trustworthy in this direction, and, secondly, that the notorious uncertainty of its preparations has thrown difficulties in the way of exact experiments or the comparison of results. It has, however, occasionally been found useful, especially if given with a corrigent like bromide to counteract its exciting effects.

An observation made by accident led me to inquire whether it could not be profitably employed for a purpose for which the physician is not often asked to prescribe, and for which, so far as I know, few if any drugs have been recommended.

It was found that a patient for whom this drug had been ordered for the relief of long-continued headache (which, by the way, it failed to accomplish) had ceased to suffer, after this prescription was made, from the bad dreams that had previously annoyed her. Acting upon this hint, it was given to one or two others who had made similar complaints, with similar results, that is, the character of the dreams changed and became agreeable.[1]

The idea which first comes into the physician's mind when he hears this complaint is likely to be that of the traditional mince-pie, or, in other words, he is very apt to attribute all bad dreams, as undoubtedly many of them ought to be, to a more or less serious indigestion or an uneasy conscience. But as it is not probable that all cases have so simple an explanation, and may not yield, any more than the insomnia which they accompany or replace, either to diet, laxatives, tonics or sincere repentance, the possibility of dealing effectually with the symptom may occasionally be welcome.

This may be a small matter; but when good restful sleep is likely to be an important or even the essential part of the cure, it is not entirely to be neglected. How often does it happen that when the patient is questioned whether he slept well, the answer comes, "Oh, I slept! but it didn't do me any good. I worked harder in my sleep than I do when I am awake."

I write this in the hope that others, as opportunity offers, may try whether this effect is a real and tolerably constant one, or whether my experience was one of coincidences only.

I may recall here the remark of Fitzhugh Ludlow, speaking, however, of much larger doses than are to be employed for this purpose, to the effect that when a second dose is taken before the effects of the first have passed off, the visions are invariably terrible.

The drug should not be given in so-called "full doses," that is, not sufficiently large to produce effects obvious to any one but the patient, and hardly even that, but just short of it. For example, if experiments have shown that ten drops of the preparation to be used gives rise, in the average person, to some excitement, rapid talking, laughter, double consciousness, etc., let the dose for the purpose we are considering be, say, six or seven. I have found that a very convenient plan of administration, admitting of varying the dosage much more easily than by the preparation of pills, which are exceedingly difficult to divide and to make up, is to prepare an alcoholic solution of the extract, which may then be dropped in the desired quantity upon a spoonful of granulated sugar. The dose is to be determined afresh for each fresh parcel of the drug used.

[1] It has acted in a similar way in one or two cases which occurred after the above was written.

Medical Progress.

REPORT ON DERMATOLOGY.

BY J. T. BOWEN, M.D., BOSTON.

CANCER OF THE SCROTUM IN CHIMNEY-SWEEPS AND OTHERS.[1]

BUTLIN undertakes an investigation of the statements (1) that chimney-sweep's cancer is rare outside of Great Britain; (2) that it is becoming less common even there; and (3) that it is, in comparison with other malignant growths, a mild one. The first proposition could only be determined by a comparison of the statistics of the London hospitals with those of the Continent and of the United States. The second proposition, that it is becoming less common, is not borne out by the statistics of the London hospitals. It was never a common disorder. The third proposition, that it is a comparatively mild disease, he assents to, regarding the prognosis of an uncomplicated cancer of the scrotum as favorable, and recurrences as less difficult to handle than is the case with most malignant affections. The disease begins by the appearance of a wart, which may remain unchanged for a long time, but finally begins to grow and to become degenerated in the centre. From the surface, where it often remains localized for a long time, the growth may extend inward and involve the testicles. Secondary affection of the inguinal glands is apt to be of late occurrence; other secondary affections are not common.

Butlin emphasizes two peculiarities of the disease, the affection of the lymph glands years after the successful removal of the primary affection, and the affection of the inguinal glands without a primary disease in the scrotum or neighboring parts. Several cases of the first sort are alluded to, and three of the second. In the second instance there is an epithelioma of the lymph glands, that presents all the characteristics of the secondary affection, but for which no primary source can be determined. Several theories in explanation of this anomaly are advanced by the author.

As to the frequency of cancer of the scrotum, Butlin shows that 39 cases have been treated in St. Bartholomew's Hospital during the last twenty years; there was a proportion of one to forty cases of malignant neoplasms. Middlesex Hospital records gave similar figures. Of the 39 cases from St. Bartholomew's, 29 were chimney-sweeps. It is believed that the skin of the sweep is so altered by his occupation that it is susceptible to the inroads of cancer, and that the skin of the scrotum is more predisposed than other parts. Of 36 deaths from cancer, which occurred in chimney-sweeps, one case presented a cancer of the lip, two of the face, 23 of the scrotum, penis and testicles. This preponderance of scrotal cancer is emphasized when one compares it with the one case of cancer of the lip that occurred, a part that is with men especially prone to cancer.

He next attempts to solve the question why the occupation should have such an influence. It cannot be the dirt, as scrotal cancer does not occur in those who follow other occupations, as miners, coal-shovellers, etc., and who are often entirely covered with dirt over the whole body. It is not possible that the soot contains the cancerous element, according to the author, nor that it is the *direct* cause of the cancerous growth. He believes that the soot must prepare the soil for the appearance of cancer by means of its chemical action. Other questions to consider, if this is so, are why chimney-sweeps of other countries are not affected with scrotal cancer. This he believes to be due to the neatness of the foreign sweeps. The Belgian and German sweeps are better protected by clothing from the soot than are the English. In Germany and Switzerland a daily bath is taken, while the English chimney-sweep washes away the soot only once a week at the most.

The question is next raised, How great is the tendency to cancer in persons with other occupations? Volkmann has written on "Tar, Paraffine and Soot Cancer," and Bell upon "Paraffine Cancer of the Scrotum." These forms are quite the same as that found in chimney-sweeps, and lead Butlin to the conclusion that it is possible to prepare the skin for the outbreak of cancer, by continuous action of certain substances upon it for a long series of years, and that these injurious substances, which we know best, are soot, tar and raw paraffine. These substances appear to exert a specific action on the tissue of the scrotum; and Butlin thinks that the susceptibility of this part depends more upon chemical and physiological peculiarities than on anatomical structure.

According to Esmarch, Langenbeck and others, the injurious agent in tobacco-smoke and tobacco-juice, is the same as that in soot; and in this way the cancers of the lip and tongue in tobacco-users are explained. He further believes that the particles of soot suspended in the air of large cities, may very easily cause cancer of internal organs, by gaining entrance into the body. He ascribes the increase in the number of cancerous affections, in part, to the daily contact of the soot with our mucous membranes.

As prophylactic, he recommends a dress for the English chimney-sweeps similar to that used in Holland, Belgium and Germany, and a daily warm bathing of the whole surface of the body.

[1] Butlin: British Medical Journal, June and July, 1892.

CONDITION OF THE BLOOD IN CERTAIN DERMATOSES.[2]

There have appeared, of late, several articles on the density of the blood and serum in different normal and pathological conditions; and Schlesinger endeavors to obtain some data as to the influence of pathological states of the *skin* on the blood and serum. His results are based on 1,200 examinations made on 200 subjects. The method of Hammerschlag was used to determine the specific gravity of the blood.

Pemphigus. — Eleven cases of pemphigus foliaceus, three of pemphigus pruriginosus and five of pemphigus vulgaris were examined. In all cases the specific gravity of the blood was much above the normal. The blood was examined both during and after an eruption, as well as during the intervals between attacks, but only slight oscillations were observed as a rule. Several times, however, very marked bullous eruptions were accompanied by a considerable increase in the specific gravity of the blood, that disappeared soon afterward. The experiments on the density of the serum showed that the increase could always be accounted for by the loss of the albuminoid constituents.

Burns. — Fifteen cases of subjects who died of burns, showed that the blood in all was very much thickened. This thickening, however, was only present during the first twenty-four hours. Sometimes in

[2] Schlesinger: Virchow's Archiv, 1892.

subjects who lived for three or four days after the burn, no thickening of the blood was observed after the first thirty-six hours. The increased specific gravity (1,065 to 1,073) was owing to the loss of serum, or at least to the loss of an albuminous fluid, provided there was no variation in the specific gravity of the serum.

Eczema. — The cases examined were generalized eczemas with very abundant secretion. Here he found only a slight increase in specific gravity, which rapidly disappeared. If the affection lasted a long time, there were found no important alterations in the blood.

In all the other dermatoses examined, lichen ruber, leprosy, psoriasis, erythema multiforme, etc., no change in the density of the blood could be detected, or there was only a change that could be accounted for by the impairment of nutrition. In lupus, the specific gravity was normal, except in cases where there had been free suppuration for a long time.

A number of examinations were made to determine the relation between the density of the serum and the liquids exuded at the surface of the skin. In vesicular and bullous eruptions, he found that the fluid contained in the bullæ was of a less specific gravity than that of the blood serum, although in certain conditions it may even exceed the latter in density. As a rule, the exudation in the dermatoses is more albuminous than that of other inflammatory processes. One hundred and thirty examinations of the contents of bullæ were made, in cases of pemphigus, burns, urticaria, erythema multiforme, erysipelas, herpes zoster, etc. He found that the contents of the bullæ in some were below the blood serum with respect to the proportion of albumen, while others, as erysipelas and vaccination vesicles, contained an equal proportion of albumen. In only one affection, herpes zoster, were the contents of the bullæ much denser than the blood serum. In two cases of pemphigus, it was found that the specific gravity of the contents of the bullæ was very high at the beginning of the process, but diminished rapidly with its extension. It was found that in exudative processes of the skin that persisted for a long time, there was no diminution in the albumen of the blood, or at most a very slight one. The specific gravity of the blood was never less than 1,027 in pemphigus and in chronic weeping eczemas.

Certain external medicaments have a marked influence on the density of the blood, raising it for several days, without especial effect on the general condition. Examinations were made on subjects who were receiving weekly injections of five centigrammes of sublimate. After each injection there was found to be a considerable increase in the specific gravity of the blood, which may be transient, lasting only some hours, or may be prolonged for several days. Two cases where the gray oil of Lang was being injected were examined, but no change in the density of the blood nor in the number of red globules was apparent. In cases undergoing the inunction cure, no important variations in the density of the blood nor in the number of red globules were observed. It was found that naphthol and chrysarobin have an action similar to that of sublimate. No especial change in the specific gravity was found in the case of twenty subjects who were being treated by pyrogallic acid. Tar on the contrary, even when used for a short time, was shown to produce quite marked variations in the specific gravity of the blood.

TREATMENT OF SYPHILIS BY BLOOD SERUM.[5]

Many pathogenic micro-organisms produce during the period of infection, soluble substances, which are capable of conferring immunity, as has been lately demonstrated. These materials circulate in the blood, and are probably eliminated by the kidneys when these organs are in proper order. Bouchaud, experimenting with the microbe of blue pus found that when he injected the urine of rabbits that had been previously inoculated with this microbe, into other rabbits, the latter were rendered proof against the action of the bacillus pyocyaneus.

It is by the action of these products that the immunity of the mother bearing a child infected with syphilis by the father, is to be explained, the placenta being the organ through which the products are carried. In this way, too, is to be explained the occasional immunity of the child of a syphilitic mother. Bonaduce also thinks it probable that in the case of a married pair, living in close relationship and contact for many years, one of whom is afflicted with leprosy while the other remains free — the reason for the latter's immunity may lie in the reception by the mother of the soluble products of the leprosy bacillus, through the utero-placental circulation.

Although the real bearer of the syphilitic poison has not been isolated, no doubt can exist in the present state of pathology, that syphilis is an infectious disease, and as such subject to the laws that hold good for others of its class. Therefore, we may assume that the micro-organism of syphilis produces, not only a syphilis poison, but also an *anti-syphilis* poison, that is to say, substances which have the power of conferring immunity from this disease. In this way the products of the microbe, that are formed in the fœtus, are the cause of the mother's immunity. In acquired syphilis in the adult it is these substances again which are formed from the microbes, and produce the acquired immunity. Thus we conclude that after a certain time, there are present in the blood and tissues of syphilitic subjects, the elements by which the organism receives its immunity from a second infection from syphilis. The quantity of the products necessary to obtain immunity in certain diseases, has been shown by experiment to be very small. Many difficulties are thrown in the way of obtaining these active products from the blood. In the first place, it is very hard to determine the point where these products are set free and enter into the circulation, and, in the second place, we find other poisonous substances in the serum of infected organisms, which favor the growth of the microbes, when injected into an animal affected with the same disease. As during the uterine life the soluble products of the micro-organisms have no outlet through the kidneys, the writer concludes that in all probability the substances that confer immunity must be present in the child immediately after birth as well as the poisons alluded to. To get rid of the latter heat is utilized. The writer, therefore, instituted the following experiment. Blood was taken from three children suffering from hereditary syphilis and left for a day in the ice-chest. In this way thirty-five cubic centimetres of serum were obtained, to which were added one hundred cubic centimetres of distilled water. This mixture was then warmed for ten minutes at 100° C., and filtered over the flame. Ten cubic centimetres of this mixture

[5] Salvatore Bonaduce: Monatsheft f. prakt. Derm., August 1, 1893.

were injected every other day into a patient who had a characteristic initial lesion and polyadenitis. The cure lasted twenty-four days, in which twelve injections were made, and during this time the ulcer and also the adenitis gradually disappeared without local treatment. Eight months later no syphilitic symptoms had appeared. The writer encourages those who have the opportunity, to institute similar experiments with the blood serum from the placentas of women who have borne children affected with hereditary syphilis.

Two eminent Italian specialists are already experimenting with blood serum in the treatment of syphilis. Tommasoli is using lamb's and calf's serum for injection, on the ground that the blood of these animals must contain a chemical substance which is hostile to syphilis, inasmuch as it is a disease peculiar to mankind alone. Pellezzari, on the contrary, thinks that the virulent agent of the disease must be attacked by the aid of the chemical products which it produces itself. With this motive, he injects the blood serum of syphilitics in the different stages of the disease. Fournier has also attempted injections of the blood serum of dogs and horses, according to the method of his colleague Richet, and Feulard has called attention to the efficacy of the dog's blood serum.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL OBSERVATION.

JOHN C. MUNRO, M.D., SECRETARY.

REGULAR Meeting, April 3, 1893.

DR. GEORGE A. CRAIGIN read a paper entitled

A CASE OF PREGNANCY COMPLICATED WITH PNEUMONIA AND EMPYEMA.[1]

DR. KNIGHT: I have been very much interested in Dr. Craigin's account of his case, one of a kind of which I have had comparatively little experience; therefore his case and the statistics and facts which he presents in regard to pneumonia and pleurisy in connection with the puerperal state are very interesting to me. In regard to the other condition, the tubercular condition, I have had a good deal of experience in cases of it which have been complicated with pregnancy, and I have come to a pretty decided conclusion in regard to such cases without having made statistics which every man ought to do if he wishes his statements to be believed. As Dr. Craigin says, it is well-known that there is a great diversity of opinion in regard to the influence of the one on the other, pregnancy on tuberculosis and tuberculosis on pregnancy. Clinicians pretty generally from the time of Cullen down have come to the conclusion that pregnancy exerts a rather favorable influence upon tuberculosis and perhaps even an arrest, whereas the obstetricians claim exactly the opposite, that the influence of pregnancy is decidedly injurious and fatal. Well, now I have come to the conclusion that this diversity of opinion comes from the fact that the clinicians see the cases early and the obstetricians see them late. It is in my opinion true that in a pretty large proportion of cases of pregnancy the tubercular process is apparently favorably influenced. There is an arrest or a great improvement during the activity of the nutritive processes set in action by the condition of pregnancy, and it is also true in my experience that very soon after childbirth and as a consequence of childbirth apparently and an attempted restoration to the normal condition of things that patients are very apt to fail rapidly; but there is an occasional exception to this and those cases you may say only prove the rule. I do not at all believe in the dictum of some French clinical professor who said the tuberculous woman may have two children or three, but never more. I remember very well reports of cases where tuberculous women have given birth to five children and been well for some time after it.

In regard to the time of the disease in which pregnancy occurs, a good deal has been said, but the fact is that it rarely happens that a woman in advanced tuberculosis of the lung becomes pregnant. I should say that a pretty good proportion of cases of tuberculous women in the earlier stages who become pregnant are likely to do pretty well during pregnancy unless they have serious digestive disturbances and those cases do very badly. If there is a good deal of nausea and vomiting and general digestive derangement during pregnancy a tuberculous woman runs down rapidly, but otherwise I should say a pretty large proportion of cases improve and some undergo a temporary arrest.

DR. S. H. AYER: I have been very much interested in Dr. Craigin's paper because I have had a case very similar to his which I reported about a year ago. Pneumonia occurring during pregnancy is a very grave complication; the mortality is very high; abortion is very apt to occur; the more advanced the pregnancy the more liable is the patient to abort, the more unfavorable is the emptying of the uterus and the more fatal the issue. The symptoms of a pregnant woman afflicted with pneumonia are not materially different from those of an ordinary case with the exception that all the symptoms seem to be very much exaggerated. The fever is apt to be higher; the skin is very hot; there is marked disturbance of the respiration. This disturbance in the respiration is due to two causes: First, the causes which are influenced by the pneumonic process, such as the exudation, the pain experienced from the coexistent pleurisy, and the using up of a great amount of oxygen, brought about by the increased combustion, due to the fever. Second, when pregnancy complicates the case we have the abdominal space filled, more or less, by the enlarged uterus pressing up the bowels, stomach and spleen, and interfering materially with the contractions of the diaphragm. Then, too, we have to take into consideration the impoverishment of the blood, which is a very important factor in rendering the case a serious one.

The case which I reported a year ago was of a young woman twenty-five years old, who, in the fourth month of pregnancy, was taken with symptoms of pneumonia, miscarrying. She remained comfortable about thirty-six hours when she was seized with severe pain in the left side, dyspnœa and fever. The symptoms were not relieved by the physician in charge, and, she being at the time under the care of a homœopathic physician, I was called to the case early in the morning of the fourth day. Examination showed signs of pneumonia at the left base. Pain was relieved by the administration of morphine and the patient very soon became in a comfortable condition. She went along comfortably until the eighth day when the signs at the left base

[1] See page 270 of the Journal.

gave way to those of effusion. In about two weeks the patient was taken into St. Elizabeth's Hospital. Aspiration was tried, but the pus would not pass through the needle, and a permanent opening was accordingly made and tubes inserted. In about six weeks the patient made apparently a good recovery, and remained well for perhaps two months longer when she again began to ail. The symptoms were obscure and in no way referable to the chest. She entered the City Hospital and remained there one month. While in the hospital a great deal of cough developed with expectoration, and she left in a very much debilitated condition having lost perhaps thirty pounds during her illness. She was looked upon as a case of phthisis. The patient then went to the country, returning perhaps in six weeks from the time she left the hospital, and again came under my care. At that time an abscess had formed in the sixth left interspace, just outside the nipple and it was evident that an empyema existed. Resection of the seventh rib was performed and in a month's time the patient was nearly well, one might say, in excellent condition. She had gained perhaps twenty pounds of flesh and the cough had entirely ceased. The diarrhœa, which had continued without interruption for two or three months, also disappeared. The marked œdema of the ankles left her and she became quite herself again. However, the opening did not close and in about one month from the performance of the resection a further resection of the fifth and sixth ribs was performed. In perhaps a month's time the opening healed entirely and the patient left the hospital perfectly well.

The subsequent history of this patient is also interesting, and I should like to repeat it here. She remained in perfect health for about fifteen months. She then became pregnant and began to have rather bad symptoms. The appetite became poor and she was troubled with more or less nausea and vomiting. The diarrhœa returned, which was not easily checked. Rather a profound condition of anæmia set in, and her general condition became very poor. At this time she was not under my observation, but, coming to Boston last October, she then being in the seventh month of pregnancy, I saw her for the first time. There was nothing noticeable then regarding her mental condition, but the anæmia, and the œdema of the ankles were present. She was put on tonic treatment and the case was supposed to be progressing fairly well. The diarrhœa stopped, and we were looking forward to a favorable termination of the case. On the 16th of December, she then being about eight months' pregnant, she suddenly developed symptoms of insanity which were of a very mild type, so mild, in fact, that the husband thought little of it. On the morning of the 17th she seemed to have hallucinations. She thought that the people were trying to get into the house; that somebody would enter the room and carry her off, and she made such queer remarks to her husband regarding their leaving the house, that he thought it best to come for me. When we returned we found she had committed suicide by the use of a razor, severing the trachea and large vessels of the neck.

I think the most interesting point regarding Dr. Craigin's paper is the fact that the patient lived at all. I think it remarkable, that, with all she went through, she survived. It seems to me, speaking in the line of criticism, that a resection would have been perhaps better than aspiration in the beginning. I firmly believe that empyema, no matter when it may occur, is a great deal better treated by resection than by aspiration, or even by a permanent opening, and it occurred to me as Dr. Craigin was reading his paper, that, possibly a resection, done in the beginning, might have in some way changed the aspect of the case.

DR. CRAIGIN: I should like to ask whether Dr. Knight thinks that if abortion were induced early in pregnancy it might affect the tuberculosis favorably.

DR. KNIGHT: I have not had any experience. I should think that the nearer a woman came to not having children the better off she would be in the end.

THE PAN-AMERICAN MEDICAL CONGRESS.

THE first meeting of this Congress was held in Washington, September 5, 6, 7 and 8, 1893, the President, DR. WILLIAM PEPPER, of Philadelphia, in the chair.

The Congress was formally opened by the PRESIDENT OF THE UNITED STATES, who said:

"The part assigned me on this occasion admits of but few words. It, however, affords me the opportunity to say how pleased I am to be in any way related to an assemblage such as this, called together in furtherance of the highest and noblest purposes and desires. I hope I may also be permitted to add that the protection of the public health and the prevention of contagious diseases are objects properly brought under consideration at the capital of a nation which appreciates fully the serious importance of everything which aids in making intercourse between civilized countries, and commerce between them safe and easy. It is also fitting that those who devote themselves to saving human life and the alleviation of human suffering should consider the modes of reaching these beneficent ends at the seat of a government whose greatest regard is the welfare and happiness of the individual citizen. It only remains for me to declare this Pan-American Medical Congress open for the transaction of the business which has called it together."

The HON. J. W. ROSS, President of the District Board of Commissioners, delivered an address of welcome on behalf of the District of Columbia.

The President of the Congress, DR. WM. PEPPER, then made an informal address, describing the objects of the Congress, and the work to be done. In conclusion, he expressed a hope that in the future the American Medical Association might expand beyond the limits of the United States, and become welded with the Pan-American Congress.

Responses were made by DR. J. W. PHILLIPPO, of Jamaica, in behalf of the British West Indies; HON. J. B. MCCREARY, of Kentucky; DR. F. MONTIZAMBERTY, of Quebec, representing British North America; DR. J. J. ULLOA, of Costa Rica; DR. J. N. HIBBERD, President of the American Medical Association; DR. C. A. L. REED, Secretary-General of the Congress; and DR. S. S. ADAMS, Chairman of the Local Committee of Arrangements.

PROF. F. A. RISQUEZ, of Caracas, Venezuela, delivered an address on "The Flora of America in its Relations to Medicine."

SECOND DAY. — WEDNESDAY, SEPTEMBER 6TH.

The formal address in the morning session was delivered by PROF. RAPHAEL LAVISTA, of Mexico, on

"The Pathology, Symptoms and Treatment of Gangrene."

Resolutions were referred to the International Executive Committee —

(1) Requesting the Committee to appoint suitable international committees on the subjects of proper Govermental recognition of State preventive medicine, on uniformity in American pharmacology, and on medical education.

(2) Resolving that the Congress respectfully recommend to her Imperial Majesty's Secretary for India these recommendations: An imperial sanitary department attached to the Government of India, a provincial sanitary department attached to each of the provincial governments, and a local sanitary department.

(3) A resolution, that in the opinion of the Section of Hygiene, Climatology and Demography, the interests of the public health in every country should be intrusted to a department of the government especially charged with their administration, and that it shall be national, that it shall have parity of voice and influence in the national councils, that it shall have independent executive authority under the limitations common to other departments, and that it shall be intrusted to educated and experienced medical men.

In the afternoon, the delegates and their families were formally received by President Cleveland.

In the evening DR. WILLIAM PEPPER delivered

THE PRESIDENT'S ADDRESS,

from which we make the following extracts:

If anything could add to the dignity of this assemblage, which for the first time asserts formally the organic union of the physicians of all America, it is the fact that the Congress of the United States passed a joint resolution requesting the President to extend those invitations, in response to which we welcome the presence here of official delegates from all the Governments of the Western Hemisphere.

After a concise review of the history of the settlement of the American Continent, and the advance of medical science, he said:

For a long time it seemed even to friendly critics that the new races which strove for a foothold on American soil were unlikely to thrive as vigorously as in their accustomed habitats, and the impossibility of developing a genuine and lasting American type was freely asserted. To those who have considered this point with anxious care, the last two decades have brought results that put to rest all apprehension. It is a demonstrated fact that the European race in America, which already numbers over a hundred millions, will show no decline in vigor or in energy, in physical or in mental strength. It is not on account of mere bigness in material achievement that we point to the millions who fought in the great civil war; or to the hundred and seventy thousand miles of railroad in the United States, almost as much as in all the world besides. It is, even more, as evidences of large imagination, of courageous resolution and dauntless tenacity of purpose, and of enormous power of physical endurance that we value the enterprises which have subjugated this continent so swiftly and are hastening its commercial consolidation.

The entire medical world was agitated during the latter half of the seventeenth century by the struggle over the merits of cinchona bark, introduced into Europe in 1640 by Juan del Vego, and no more convincing tribute can be adduced as to the value of medical and sanitary science than the prominent place occupied by malarial diseases in the general and medical literature of the seventeenth and eighteenth centuries as contrasted with the feeling of impunity with which they are now regarded. Among the results which may be anticipated from this meeting is, I trust, the adoption of some well-considered plan for systematic conjoint study of our American remedies to greater uniformity in their preparation, and ultimately to a single pharmacopœia for the entire continent.

The introduction of nitrous oxide (1844) and of ether (1846) into medical practice, with which the names of Wells and of Morton are so honorably connected; the establishment of the operation of ovariotomy by McDowell, of Kentucky, upon a secure scientific basis — these and hundreds of other achievements are too familiar to need mention. Every one knows now how superfluous it is to say a word in defense of American literature, and certainly we who know how powerfully the opinions and practice of medical men in Europe and throughout the world are influenced by American writings may view our position with some complacency. Yet a survey of what America is actually contributing to medical literature shows clearly how far we are behind the nations which lead in medical thought.

On the other hand, in the more ephemeral forms of medical literature the figures are very different. From a careful count made of the volumes of medical journals and transactions filed in the library of the Army Medical Museum at Washington, it is clear that of these classes of medical literature there were, in 1890 and in 1891, published in America about twice as many volumes as in Germany or France, and fully three times as many as in Great Britain. We must not forget that in the hurry of our life of to-day many observations and investigations of great value are published in journals, instead of being reserved to become part of more serious and complete volumes. But the great excess of medical journals in America, as contrasted with the comparatively small number of new medical works, is entirely consistent with the admitted leadership of Germany, France, and Great Britian in medical science. The apparently extraordinary number of medical journals in America is due chiefly to a substantial reason, and one which influences equally the existence of very numerous medical schools and medical societies. The vast extent of territory and the relatively sparse population render it impossible to serve the country with as low an average of medical men, schools, societies, or journals as is possible in more densely-populated countries.

The rapid rise in the standard of scientific requirements, both of medical men and medical literature, and the increasing appreciation on all sides of the fact that the higher medical education is the true interest both of the profession and of the public is accomplishing the much-needed work of checking the ill-considered establishment of new medical enterprises. I should fail in courtesy and in candor alike were I not to acknowledge the great value of the example which has been so consistently set by Latin-America and by Canada in the maintenance of a high standard of qualifications for medical practitioners.

A broad field opens before us for the study, with the aid of collective investigation, of the distribution and course of phthisis and rheumatism and other important

diseases as influenced by race and locality. The endemic fevers, other than malarial and typhoid and yellow fever, which are said to prevail in various parts of North and South America, have long demanded systematic investigation to complete the study which the illustrious Drake began.

Our combined influence will be irresistible when used in advocacy of higher education; in carrying out large plans for the scientific study of our national life, as affected by social and climatic influences; in the adoption of remedies and remedial measures of demonstrated merit, and in the insistence upon a fuller recognition of the lofty function of preventive medicine. "Salus sanitasque reipublicæ, suprema lex." Let us acquire here a closer touch with each other, a deeper faith in our profession and its noble destiny, and a stronger determination to labor in brotherly co-operation for the loftiest ideals of service to science and the race.

(To be continued.)

Recent Literature.

Cholera: Its Protean Aspects and Its Management. By Dr. G. Archie Stockwell, F.L.S. In two volumes. Physicians Leisure Library. Detroit: George S. Davis. 1893.

Dr. Stockwell's views in regard to the pathology and treatment of cholera are not those most generally held at the present time. According to the views which he advocates, cholera is a neurosis. The sympathetic system is in either a paralytic or hyperæsthetic condition — extremes which meet. The pneumogastric, a cerebro-spinal nerve, is an antagonistic and controlling agent; its stimulation, and thereby the re-establishment of its cardio-inhibitory functions, is an important indication. In all attacks of cholera, regardless of the stage, the first indications are to stimulate the vaso-inhibitory apparatus and antagonize the sympathetic (especially in its cardiac and lobar plexuses) by sedation, by reflex, or by both. Irritants or epispastics over the branches of the vagus in the neck beneath, in front of and behind the ear, covering three inches of surface, preferably on the right side, should be freely applied. The effect is almost instantaneous.

The so-called cholera-bacillus of Koch, Dr. Stockwell regards only as an old friend under a new name — an everyday *spirillum*. He makes no distinction, except in severity, between cholera nostras and Asiatic cholera.

The second volume is largely made up of extracts and quotations from writers on cholera whose opinions commend themselves to Dr. Stockwell.

Should this book reach a second edition, more careful proof-reading would be desirable. A constant repetition of *prima viæ* strikes the reader as strangely as do some of the author's opinions.

Cholera: Its Causes, Symptoms, Pathology and Treatment. By Roberts Bartholow, M.D., LL.D. Philadelphia: Lea Brothers & Co. 1893.

This small octavo of 130 pages contains in a condensed form a well stated *résumé* of all the important and practical points in regard to cholera which the practitioner or student requires. There is a judicious historical introduction; and the author's personal experience in two epidemics has well fitted him to weigh the value of recent investigations and procedures.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, SEPTEMBER 14, 1893.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

AUTO-INTOXICATIONS IN MENTAL DISEASES.

There has been of late considerable speculation respecting auto-intoxications in the psychoses. Such speculations have been stimulated by Professor Bouchard's researches on the pathogenic rôle of the auto-intoxications in general.

Dr. Kellogg, of Flushing, N. Y., in the New York *Medical Journal* "considers it probable that a considerable proportion of mental disorders have a toxic origin." In alcoholic, saturnine, and some other forms of poisoning the dependence of the mental disturbance upon the poison is recognized, and he contends that certain auto-intoxications with ptomaines are probable causes of insanity. The toxic albumoses have been found in the urine in cases of insanity. Why, he asks, may not the autogenous poisons enter the circulation and act directly upon the central nervous centres with sufficient toxic force to produce mental disturbance?

Dr. Rohé, of Catonsville, Md., in inquiring into the relations existing between pelvic disease and psychical disturbances in women,[1] points out the frequency with which bodily conditions influence mental states, and shows that "a torpid condition of the intestines, Bright's disease, putrefactive processes in the intestinal canal, etc., might give rise to melancholia and other disorders of the mental functions."

Dr. H. M. Hurd in an article "On Post Febrile Insanity" in the *Journal of Insanity* studies the delirium of fevers and the psychoses developing from specific infections, and Dr. G. T. Tuttle, of Somerville, Mass., reports the results of the examination of the urine in two hundred consecutive cases in the McLean Asylum.[2] Albumen and casts were found in 55 cases, albumen alone in 64 cases. He collects statistics from various pathological reports of hospitals and finds that in about 40 per cent. of autopsies in the insane, kidney disease was found, and concludes that chronic nephritis [uræ-

[1] Journal of the American Medical Association, September 24, 1892.
[2] Journal of Insanity, April, 1892.

mic poisoning] is sometimes the cause of mental aberration which may be called insanity.

The subject was discussed at the Fourth Congress of Mental Medicine held at Rochelle in August, 1893. Regis, of Bordeaux, and Chevalier-Lavaure, referees, stated that they had been working on the line of the autogenous poisons, and had made many chemical and clinical researches to elucidate the relation of auto-intoxications to mental diseases. The toxicity of the urine was found to be diminished in maniacal states and augmented in melancholia. The urine of maniacal patients when injected in animals produces excitation and convulsions; that of melancholic patients, restlessness, dejection and stupor. There is often in insanity as in eclampsia an inverse relation between the toxicity of the urine and that of the blood, the latter being hypotoxic when the urine is hypertoxic, and *vice versa*.

Under the head of "Facts of Clinical Order," these authors consider the psychoses of acute infectious diseases, of visceral diseases, and of diathetic diseases:

(1) In respect to the psychoses of infectious diseases (typhoid fever, eruptive fevers, influenza, erysipelas, cholera, puerperal fever) the sum of researches thus far made goes to show: First, that from a pathogenic point of view, these mental disorders are the result either of direct action of microbes or of their indirect and mediate action by the toxines which they secrete; second, that from a clinical point of view, they may present two aspects. In the febrile stage, the psychosis is an acute delirium, resembling the alcoholic; in the post-febrile stage, it is of an asthenic character, a state of mental obnubilation and confusion (Verwirrtheit). The referees think that a third form of infectious psychosis must be admitted, a form intermediate between those above mentioned, with the symptomatology of paralytic dementia, and which they call pseudo-general paralysis, or infectious general paralysis; and they ask in this connection, if most cases of typical paralytic dementia may not be the consequence more or less remote of an infectious disease? However this may be, the characteristic symptom of infectious psychosis, in all its forms, seems to be intellectual disorder, mental confusion, without doubt the result of the impregnation of the temporary inhibition of the cerebral cells by toxic agents. Generally the psychosis thus produced is susceptible of cure.

(2) The visceral psychoses are also believed to be in great measure the consequence of auto-intoxication. Nevertheless, experimental researches have not been pushed far in this direction, and in what concerns particularly the psychoses resulting from digestive disturbances, we yet know very little, having only certain imperfect data as to the concomitant alterations of the gastric chemism and the toxicity of the intestinal contents. We have more satisfactory data regarding hepatic and nephritic insanities, and it is clearly established to-day by the researches of French authors that these psychoses are at their highest mark the result of an autochthonous poisoning of the organism, of an auto-intoxication. As for the clinical character of these visceral psychoses, it may be affirmed that in cases where the intoxication is acute, the mental disease manifests itself habitually under the form of an acute toxic delirium like alcoholic delirium (this is the case in uræmic poisoning); when the intoxication is slow and chronic the state is one resembling melancholia, or, more rarely, paralytic dementia.

(3) The diathetic psychoses resemble acute toxic delirium, and in the interval of attacks they frequently manifest themselves under the form of general paralysis or paroxysmal mania more or less periodical, and almost always with melancholic character. The referees have also noted that these paroxysms of madness appear to correspond to variations in the composition of the liquids of the organism (hypoazoturia, hypophosphaturia, oxaluria, etc.), notably to discharges of uric acid, frequent precursors of the end of the crisis, and also to modifications in the urinary toxicity which is found to be inferior to the normal.

Under the head of "Facts of Therapeutical Order," the referees state that the antiseptic treatment, general or local, often gives most excellent results.

It is true that in the treatment of the psychoses of acute infectious diseases a tonic and supporting regimen is necessary to combat the state of exhaustion and inanition, the agents of infection being unknown; but in the visceral psychoses, linked to diseases of the stomach, liver, kidneys, etc., very good results have been obtained from the employment of purgatives, lavage of the stomach, and antiseptics.

At the same meeting, Ballet, of Paris, gave some interesting facts concerning the toxicity of the urine of insane persons, which were strikingly confirmatory of data previously furnished by other authorities. At the same time, he cautions against exaggerating the importance of these researches; the study of urinary toxicity in the insane has without doubt its utility, but it would be impracticable to found nosological distinctions on this alone. In one instance, cited by him, the toxicity of the urine was extreme, the patient was an hysterical girl who manifested no delirium or mental aberration, and had no apparent disorder except hysteria.

VARIATIONS IN INTENSITY AND RHYTHM OF THE CARDIAC PULSATIONS.

ALTHOUGH in general variations in the intensity of the heart sounds depend upon the strength of the systole, there are a number of other circumstances which may cause variations. Potain[1] finds that among the most obvious of these are increase in thickness of the cardiac walls, or those of the chest, the interposition in front of that organ of gas or liquid or the presence of a portion of the lung, possibly in an anomalous anatomical position. Special sounds may be accentuated in certain diseases, as the aortic sound in Bright's and the pulmonic where there is an obstacle in the pulmonary circulation.

[1] L'Union Médicale, January 5, 1893.

In most cardiac affections there is great acceleration of the rate, though sometimes retardation is observed. The latter, however, does not usually depend on a lesion of the orifices, and is often more apparent than real, some beats being too feeble to be felt in the pulse or even to be heard by attentive auscultation. This condition has great prognostic value as it indicates a change for the worse in the condition of the patient. The fœtal rhythm, recently insisted upon by Huchard, depends upon an accelerated cardiac action accompanied by a modification in the duration of the pauses, so that the intervals between the two sounds seem of equal length.

Irregularity of action may depend on simple digestive disturbances, especially intestinal, but is usually a symptom of valvular lesion and it is well worth knowing that it is observed especially in patients who have been under treatment by digitalis.

At times three, or even four, sounds, may be heard with each cardiac revolution, at others, only one, in the latter case it is usually the first sound which is lost or rather becomes so faint that it cannot be heard. Reduplication may be normal and is then dependent on the respiratory movements, the reduplication of the second sound being produced at the end of inspiration and at the commencement of expiration, while the reverse is true for that of the first. The reduplication of the second sound is due to the premature closure of the aortic flaps from the increased tension of the blood in that vessel, and results from purely mechanical causes. The physiological reduplication of the first sound is much rarer. The pathological reduplication of the second sound may be the only sign of mitral stenosis, which otherwise gives no evidence, either general or local, of its presence. It is independent of respiration and accompanies all cardiac pulsations. Being due to changed conditions of pressure in the two arteries, at the beginning of the disease it is due to premature closure of the aortic valves, at the end to premature closure of the pulmonic; midway in the course of the affection there is no reduplication, but only an accentuation of the second sound. The reduplication of the second sound due to premature aortic closure is also seen in general pericardial adhesions, and the differential diagnosis can only be made by looking for other signs of this condition. The two conditions may, of course, be co-existent.

MEDICAL NOTES.

Typhus Fever. — Typhus fever has broken out again in San Luis Potosi, Mexico, and a large number of deaths occur daily. The other cities are so far free from the disease.

Cholera. — The last week has seen a general improvement in the cholera epidemic throughout Europe. At present the condition is most serious at Soolina and the Danubian ports. Kalafat, Styrna and Scutari are all infected — over three hundred cases having been reported in the last week with a high mortality. The disease has appeared in Bucharest and in the prison at Constantinople. The mortality throughout Turkey is about thirty per cent. Another death is reported from Vienna. In Roumania there have been fewer cases the last week than previously. In Italy and Southern France there has been a rapid decline in the epidemic. Nantes is the only place in France at present seriously affected. Thirty-five cases have occurred in Antwerp, since July 28th, with eighteen deaths. They have been scattered, and chiefly among sailors. The sanitary condition of the city is reported as very poor, no radical improvement having been made since last year. In England a death from cholera occurred the 11th inst. at Retford, County Notts.

The South Carolina Disaster. — The sanitary condition of the whole Carolina coast, resulting from the hurricane of two weeks ago has become most serious. Physicians in the vicinity of Beaufort and St. Helena are reporting to the Marine-Hospital Service a very large number of diarrhœal and malarial cases. It is almost impossible, they say, to care for the sick, and to provide the necessary disinfectants. The President has detailed a medical officer to take charge of the sanitary measures at Beaufort, and has placed a revenue cutter at his disposal.

Negro Surgery. — An article is going the rounds of the English newspapers describing "a wound in the heart of a negro successfully treated at the Negro Hospital, Provident, U. S. A., by a negro surgeon, assisted by negro nurses." American medicine is fairly well specialized already, but this suggests a new line for division of practice.

Pasteur Institute Report. — According to the report of the Pasteur Institute of Paris, for 1892, there were 1,793 persons inoculated who had been bitten by rabid animals. Seven patients died, a mortality of 0.39 per cent., which should be really considered lower, as three of the seven were already showing symptoms of hydrophobia when first treated. Bites about the head and face have the worst prognosis, a mortality of 1.48 per cent.

The Cure of Hay Fever. — The treatment of hay fever is subject to criticism such as comes to no other disease, namely, from societies of the sufferers themselves. It is interesting to note that the patients are not as enthusiastic over, and do not report such good results as a society of their medical advisers would be likely to do. The United States Hay Fever Association have recently held their annual meeting in Bethlehem, N. H., and listened to papers largely on the disease from the patients' point of view. It appears to be the general opinion that the only certain relief is to be found in the White Mountains, and that most therapeutic measures are of little or no use, and some of them harmful. The treatment by local cauterization in the nose is often of benefit, but the benefit is generally only partial and temporary.

NEW ENGLAND.

FOREIGN MEMBERS OF THE PAN-AMERICAN CONGRESS. — The foreign members of the Pan-American Medical Congress were the guests of the physicians of Boston this week. Tuesday morning they visited the Massachusetts General Hospital. At noon they were given a luncheon by the Faculty of the Harvard Medical School, in the school building, about one hundred and fifty guests being present. In the afternoon they were shown over Harvard College. Wednesday morning they spent at the Boston City Hospital where they were given a luncheon by the Trustees. In the afternoon they were shown the harbor and quarantine arrangements as the guests of the Board of Health. Several of the members were accompanied by their wives and daughters, who were given a carriage ride about the city while the physicians were visiting the hospitals.

FRUIT AND CHICKEN NUISANCES. — The Board of Health of Boston has had much trouble lately with fruit venders and Chinamen who keep fruit to ripen, or slaughter fowl in their houses in violation of the city ordinances. This week several fruiterers have been convicted and fined for this offence, and the Chinese who keep fowl and kill them to order were also convicted, but no sentences imposed, as the Chinamen desired to confer with the Board upon some place where they may kill their fowl according to their national custom. This action of the court is expected to strengthen the control of the Health Board in abating such nuisances.

THE BOSTON WATER-SUPPLY. — The quarterly analysis of the Boston water-supply has been received by the Water Board from Dr. Wood. The waters are reported as generally containing less chlorine than formerly. The water improves on passing through Basin No. 3 and the Sudbury aqueduct, but does not improve in passing through the other basins and conduits. The waters of Stony Brook, Lake Cochituate and Basin No. 4 are about the same as in July, 1892, except that they have less chlorine. Basin No. 3 water has less chlorine than ever before. The waters of Basin No. 2, Farm Pond and Beaver Dam Brook are about the same as in July, 1892. The waters of Basin No. 2 and of the service has a little more albuminoid ammonia than for two years. The water of Chestnut Hill Reservoir is about the same as last October, and that of Cold Spring Brook about the same as in April 1892.

SCARLET FEVER AT PROVIDENCE. — An unusually large number of cases of scarlet fever have occurred in Providence, R. I., the last three weeks, and several cases have been reported from Pawtucket.

THE EPPING CAMP-GROUND. — There seems to be good reason to suspect the sanitary condition of the Epping camp-ground near Amesbury, Mass. Last year several cases of typhoid, five of which were fatal, occurred among the campers soon after the season. This year a similar outbreak of the disease has begun, and one death has already occurred.

Miscellany.

THE DENTAL CONGRESS.

THE International Dental Congress which was opened in Chicago on August 14th, deserves more than passing notice on account of the character and excellence of the work done, and the size of the attendance. In addition to an attendance of 1,000 from the United States, 116 foreign members were registered, the latter not including Americans practising abroad. At the banquet held towards the close of the meetings twenty-seven different nations were represented in the responses.

The scientific work of the congress was done in eight sections; and the character of the work was extremely satisfactory. It is interesting to note that the more scientific of the papers attracted the largest audiences. The historical addresses are of interest to the physician as well as the dentist, in tracing the birth of dentistry from medicine and its rapid growth to its present position. The inaugural address of the President, Dr. L. D. Shepard, traces this development clearly and concisely from the opening of the first dental college, in Baltimore, in 1839, to the present day. The first dental journal was established in the same year, and in 1840 the first dental society. In 1841 the first State dental law was enacted, in Alabama, and, curiously enough, remained the only one in this country for twenty-five years, when New York followed in 1868. The English law was enacted in 1878, and other countries a little later.

Surgical anæsthesia, by which medicine has gained even more than dentistry, was given to the world by the younger profession. The greater honor is perhaps due to Dr. Wells, provided it is true that, in 1844, two years previous to Dr. Morton's discovery, Dr. Wells did intelligently and publicly, with full appreciation of the phenomena, perform painless operations in dentistry and surgery by the administration of nitrous oxid gas, given for that specific purpose. Dr. Morton probably knew of Dr. Wells's work previous to 1846. It is a curious fact that after the introduction of ether in 1846 and of chloroform in 1847 the use of nitrous oxid was not revived until 1862.

Among other discoveries of importance in dentistry may be mentioned the cohesiveness of gold. This was followed by improved instruments, the mallet, the rubber dam and the engine, and the preservation of teeth more and more superseded the older artificial plates. Dentistry has profited by the advances of recent medicine, and antisepsis and the study of bacteriology. To what a degree of progress the science of dentistry has arrived may be inferred from the list of papers presented to this congress.

THE OPERATIVE TREATMENT OF PERITONEAL TUBERCULOSIS.

THE value of operation in the treatment of peritoneal tuberculosis in children has been much disputed and even yet is by no means generally allowed. The numerous cases benefited by laparotomy have been challenged as to correctness of diagnosis and the indications which predict a favorable result not thoroughly understood. The report by Conitzer[1] of seven cases

[1] Deutsche Med. Wochenschrift, No. 29, 1893.

operated upon for tuberculosis of the peritoneum throws some light upon the points in dispute.

The children varied from two and a quarter to nine years old. Four cases were of the exudative form in which there was a diffuse superficial inflammation of the peritoneum with numerous very small tubercles upon the parietal and visceral membrane and free serous fluid in the abdominal cavity. In all of these cases there was but slight disturbance of the general health. Some anorexia and heaviness and disinclination to move about were the chief symptoms. Some of the patients, too, had gray colored stools though not otherwise icteric.

The other three cases were of the dry adhesive form in which there was more general disturbance and often pain, and a considerable degree of matting together of the intestines and omentum.

The operation consisted only of an incision into the abdomen, and, after allowing the free fluid to escape, closing up of the wound. No washing or manipulation of the cavity was done in any case.

The four exudative cases all made a lasting recovery. In each, microscopic examination of the tissue showed characteristic tubercular structure, giant cells and in two cases the presence of bacilli. The three other cases all showed caseous tubercular nodules with bacilli. One case recovered from the operation and after four and a half months was still relieved from much of the pain and discomfort though not at all well. The other two cases died with little or no relief.

After discussing these cases in detail he draws the following conclusions:

(1) Peritoneal tuberculosis is spontaneously curable: the dry form in very few, the exudative form in a very large number of cases.

(2) All forms may be cured or at least relieved by laparotomy, even when other treatment, including puncture, has failed.

(3) The results of the operation depend upon (*a*) the form of the disease, the best results being obtained in the cases of effusion, (*b*) the duration of the illness, (*c*) eventual complications.

(4) The operation is contraindicated in advanced cases or those with marked tuberculosis of other organs.

(5) No explanation can be given of the reason or manner of the curative effect.

LINGUAL TRACTION IN CASES OF SUSPENDED RESPIRATION.

The Académie de Médecine has recently had under discussion the reports of many cases of asphyxia treated according to a method first suggested in July, 1892, by M. J. V. Laborde. At that time he reported several cases of apparent death from drowning, successfully treated by rhythmic tractions upon the tongue, drawing it well out of the mouth and allowing it to fall back again about fifteen times a minute. The result was so satisfactory that the method was tried in cases of asphyxia of the new-born, of gas poisoning and strangulation.

Since then a more general trial has been made by other physicians, and laboratory experiments to determine the physiological action of the treatment have been carried on. The results as reported to the Society[1] are full of interest. The procedure is as follows: The patient is laid upon the back with the head low or very slightly raised on an even plane from the hips. The mouth is opened and the tongue firmly seized between the thumb and forefinger, pretty well back. It is then drawn forcibly forward out of the mouth till some tension is put upon the root. It is not sufficient to draw forward the tip alone. The tongue is then allowed to fall well back into the mouth. This alternate traction and replacing of the tongue is done regularly about fifteen times a minute until the patient begins to breathe. In the cases reported as successful, the time occupied in traction varied from three minutes to two hours, according to the severity and nature of the case. When the lungs hold fluids, as water or mucus, a brief time should be spent in emptying them before beginning traction. The first sign of returning life is to be looked for in an epigastric wave caused by a slight diaphragmatic contraction. Following this a faint sigh gives evidence of a respiratory attempt. Diaphragmatic respiration returns first — then the thoracic. In severe and prolonged cases some observers found advantage in the coincident application of thoracic pressure. Many of the cases reported responded successfully to the Laborde treatment, after failure of other methods. This was especially so in cases of natal asphyxia in which the tongue traction was tried after the usual obstetrical methods had proved insufficient.

One case was particularly interesting. A girl, thirteen, was seen three minutes after apparent death from tuberculous meningitis. The body was still warm and slightly cyanotic, the pupils dilated, no breathing existed, nor could any cardiac action be made out by auscultation. Rapid traction of the tongue was tried, forty times a minute. After three minutes there was less cyanosis. Soon slight nasal dilatation was noticed; then the epigastric wave of slight diaphragmatic contraction, followed by thoracic motion. A faint murmur was heard over the heart and a small radial pulse made out. At the end of ten minutes the respiration was re-established (both abdominal and thoracic) the heart's action could be felt and both sounds made out.

This condition lasted for five minutes and then in spite of continued traction the vital processes disappeared in the reverse order of their re-appearance and the patient died permanently.

The physiological mechanism is through a reflex stimulation of the excito-motor forces of respiration. The sensory nerves of the tongue, especially at the base, are stimulated by the traction. The superior laryngeal is the most important, the glosso-pharyngeal and lingual playing a secondary rôle.

In dogs a section of the laryngeal nerves made the subsequent traction of the tongue during asphyxia of very slight effect, though previously the same dogs had responded well. The ninth nerve is second in importance. The motor nerve essential to the reflex, is the phrenic, as after section of this nerve in dogs continued and energetic traction of the tongue called forth not the slightest response.

The method promises so good results that in the official directions of the second regiment of *pontonniers*, for the treatment of persons drowned, the government has placed lingual traction as the first means to be employed.

Deaths reported 3,459: under five years of age 1,717; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhœal diseases, whooping-cough, erysipelas and fevers), 952, diarrhœal diseases 653, consumption 329, acute lung diseases 204, diphtheria and croup 107, typhoid fever 91, whooping-cough 40, scarlet fever 23, cerebro-spinal meningitis 22, malarial fever 9, measles 5.

From whooping-cough Chicago 12, New York 9, Philadelphia 6, Pittsburgh 4, Washington and Cleveland 2 each, Brooklyn, Boston, Cincinnati, Milwaukee and Charleston 1 each. From scarlet fever Boston 4, New York, Philadelphia and Pittsburgh 3 each, Chicago and Cleveland 2 each, Milwaukee, Nashville, Lowell, Lynn, Woburn and Medford 1 each. From cerebro-spinal meningitis Chicago 6, Cleveland 4, New York and Washington 3 each, Brooklyn and Worcester 2 each, Lynn and Somerville 1 each. From malarial fever New York 5, Nashville 2, Philadelphia and Charleston 1 each. From measles New York 2, Brooklyn, Boston and Washington 1 each.

In the thirty-three greater towns of England and Wales with an estimated population of 10,327,846, for the week ending August 26th, the death-rate was 21.6. Deaths reported 4,283; acute diseases of the respiratory organs (London) 162, diarrhœa 707, whooping-cough 74, diphtheria 66, measles 62, scarlet fever 55, fever 55, small-pox (London 3, West Ham, Leicester, Oldham and Blackburn 1 each) 7.

The death-rates ranged from 13.4 in Croydon to 33.2 in Blackburn; Birmingham 21.8, Bradford 26.4, Derby 17.1, Halifax 18.7, Hull 27.0, Leeds 24.8, Leicester 20.3, Liverpool 23.8, London 20.8, Manchester 24.4, Newcastle-on-Tyne 22.5, Nottingham 18.0, Sheffield 28.0.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT. U. S. ARMY, FROM SEPTEMBER 2, 1893, TO SEPTEMBER 8, 1893.

A board of officers to consist of COLONEL JOSEPH C. BAILY, assistant surgeon-general; MAJOR CALVIN DEWITT, surgeon, and MAJOR HENRY M. CRONKHITE, surgeon, is appointed to meet at the call of the president thereof, at San Antonio, Texas, for the examination of such officers as may be ordered before it, with a view of determining their fitness for promotion.

CAPTAIN HENRY S. KILBOURNE, assistant surgeon, will report in person to COLONEL JOSEPH C. BAILY, assistant surgeon-general, president of the examining board, appointed to meet at San Antonio, Texas, for examination for promotion.

CAPTAIN MARCUS E. TAYLOR, assistant surgeon, having been found by an Army Retiring Board, incapacitated for active service, is granted leave of absence until further orders, on account of disability.

Leave of absence for four months, to take effect on or about October 25, 1893, is granted FIRST-LIEUT. ALLEN M. SMITH, assistant surgeon, U. S. A.

CAPTAIN JULIAN M. CABELL, assistant surgeon, is relieved from duty at Fort D. A. Russell, Wyoming, and ordered to Washington Barracks, D. C., for duty with the company of instruction of the hospital corps.

RECENT DEATHS.

CHARLES W. PARSONS, M.D., Professor of Physiology in Brown University, died at Providence, R. I., September 2d, aged seventy years. He was the recipient of the Fisk Fund Prizes for 1848 and 1854. He was a member of the class of 1840, Harvard College.

AUSTIN K. GOULD, M.D., died at Worcester, September 8th, aged sixty-seven years. During the War of the Rebellion he served as surgeon in charge of a division hospital at Baton Rouge and at Wilderness Run. He was a prisoner for several months at Andersonville.

W. M. GRAILY HEWITT, M.D., Consulting Obstetric Physician to University College Hospital and Emeritus Professor of Obstetric Medicine in University College, died in London, August 27th, aged sixty-five years. He contributed many papers to obstetrical and gynecological literature. He was lately President of the Obstetrical Society of London and an honorary member of the American Gynecological Society.

BOOKS AND PAMPHLETS RECEIVED.

Pneumonia Among the Insane. By Eliot Gorton, M.D. Reprint. 1893.

Suturing the Tendo Achillis in the Correction of Deformities of the Feet. By H. Augustus Wilson, M.D. Reprint. 1893.

Therapeutical Superstition. By Geo. T. Welch, M.D., Ex-President of the New Jersey State Medical Society. Reprint. 1893.

Gilman Currier, M.D., Visiting Physician to the New York City Hospitals; Fellow of the New York Academy of Medicine; Member of the New York Pathological Society; Member of the American Medical Association, etc. New York: E. B. Treat. 1893.

Lectures.

MEDICAL EDUCATION IN THE UNITED STATES.[1]

BY J. COLLINS WARREN, M.D.,
Professor of Surgery in Harvard University, President of the Section.

GENTLEMEN: — The work of this Section is of a character which does not usually form a prominent part in the proceedings of medical gatherings.

In almost any department of education, pedagogy or the science of teaching is a recognized specialty.

The rapid progress which has been made in medical education in this country within the last few years has brought about such profound changes in methods of instruction, and the strides which medical science is making all over the civilized globe are bringing into view so many new fields of work, that the teachers of to-day have a far more complex and difficult task than was presented to their predecessors. The art of teaching medicine has not been taught, in this country at least; the time has arrived to take up the subject.

In introducing such a subject as this, it seems appropriate to take a brief retrospective glance at the history of medical education in this country.

There lies before me as I write, a quaint little volume entitled, "A Discourse upon the Institution of Medical Schools in America," published in 1765. It bears the following inscription:

"To Doctor John Warren, Physician in Boston, This Copy is presented by his respectful and affectionate Friend, John Morgan, Philad'a, Feb. 27, 1783." This book may be safely regarded as the first contribution to the subject which we are to discuss today and the two dates are memorable; the former indicating the foundation of the medical department of the University of Pennsylvania, and the latter the birth of the medical department of Harvard University.

Dr. Morgan justly remarks that "medicine is a science as important in its object as it is difficult in the acquisition. It is very extensive in its researches and presupposes the knowledge of many other sciences. The cultivation of it requires no small abilities, and demands of those who engage in the arduous pursuit an enlarged and benevolent mind."

It is interesting to note that one whom we might justly look upon as the father of medical education in this country and who "had spent five years in Europe under the most celebrated master in every branch of medicine," should have taken so optimistic a view of the knowledge of medicine at that time as to say: "The industry of many centuries has already been employed to bring Physic to that degree of perfection at which it is now arrived." Fortunately he adds: "It will still require a long time to remove the obscurities which yet veil many parts of it."

Three years after this book was written, Pennsylvania held her first medical commencement and the provost justly remarked: "This may be considered the birthday of medical honors in America."

The men who started this movement had received much encouragement from across the ocean and the remark of one of their teachers, Dr. John Fothergill of London, is of special interest to those concerned in the work of this congress. Writing to James Pemberton in 1762 he recommends Drs. Shippen and Morgan as men well qualified for the work of teachers, "both of whom," he says, "will not only be useful to the province in their employment but if suitably countenanced by the legislature will be able to erect a school of physic among you that may draw students from various parts of America and the West Indies."

During the colonial period of our history it was the custom for young men who entered upon the study of medicine to become regularly apprenticed to some practitioner for a term of three or four years during which time the preceptor was entitled to the students' services in preparing and dispensing medicine and serving as an assistant in minor surgical operations. As a return for this, the physician was obliged to give the student detailed and thorough instruction in all the branches of medicine. Many of the leading men frequently had several students in their office, constituting a small class, who were drilled as regularly in their studies as they would be in college. In some instances the term of apprenticeship was extended even to six or seven years.[2]

When the medical school sprang into existence it was at first intended merely to supplement the apprentice system, and as means of communication of one part of the country with another were exceedingly limited it was found desirable to concentrate school work into as small a part of the year as possible. Hence the origin of the short term of four months which has clung so persistently to the American system.

I will not undertake to weary you with a detailed account of the history of the development of our system of education. Suffice it to say that the close of the century found schools established not only in Pennsylvania and Massachusetts but in New York, Maryland and Vermont. There were, however, in 1810 only five medical schools in existence with an aggregate number of medical students of about 650, of whom 100 received the degree either of bachelor or doctor of medicine. The bachelor's degree was given to those who had attended one full course of college instruction. It was hoped that such students after a short period of practice would eventually return to take the higher degree, but as this expectation was not fulfilled the degree of bachelor of medicine was soon wisely abolished.

A noticeable feature of the education of that early period in our medical history were the requirements for a high standard of general education. Those students who did not possess a college degree were expected to pass an examination in Latin, mathematics and "Natural and Experimental Philosophy."

To obtain the degree of doctor of medicine it was necessary that the applicant should have been a bachelor of medicine for at least three years, should have attained the age of twenty-four years and should write and defend a thesis publicly in the college.[3]

When we consider how imperfect was the knowledge of chemistry, physiology and even anatomy, and many other branches of medical science, and how little of what we now consider the foundation of medical education there was to teach — such a course cannot be regarded as a very complete and exacting one.

"Under these influences the first thirty years sufficed to cause the bachelor's degree to be abandoned by all the schools, the number of professors in each

[1] An Address delivered before the Section on Pedagogy of the Pan-American Medical Congress.

[3] William Pepper: Higher Medical Education, 1877.

school to be double, and the length of the annual college term to be shortened one-third." (Davis.)

Such was the standard of education with which the present century opened. New schools continued to be created, not infrequently in connection with some university, as in 1810 at Yale University, in 1817 in Lexington, Ky., in 1820 at Brunswick, Me., in 1825 at Charlottesville, Virginia, until in 1840 twenty-six new medical colleges had been added to the list, the whole number of students in the country amounting to 2,500, the population in that year being 17,069,453.

A glance at the report of a committee to the Medical Society of the State of New York in 1833, gives a good idea of the amount of work done by the schools at that period.

In the twenty schools mentioned in this report the number of courses of lectures required was two, with one exception — that of the University of Virginia, where three courses were required; and to the credit of this university be it said, the length of each course was ten months, whereas, the almost invariable custom of the other schools was to give a course of four months' duration only. The time of study purported, however, to be in all cases three years, "including the time devoted to lectures," as is stated in most of the reports. This straw indicates that at that time the chief dependence, or nearly so, was placed upon the extra-mural instruction which was given to the student. At Yale University there was this additional requirement, namely, that the student was required to study four years "if he had not graduated," which phrase, I presume, means if he had not already taken the academic degree. This seems to be the first intimation that a longer term than the standard then set was necessary for a complete equipment for the practice of medicine.

The Medical Institution of the State of Georgia (incorporated in 1828) gave at first the bachelor's degree with one year of study, but immediately abandoned it for the usual curriculum.

In the University of Pennsylvania, to which we look for the standard in these early, as well as later days, two full courses were required, but as in many other schools one course only was demanded from those who had attended a course at some other reputable school. In addition, a course of clinical instruction in one of the Philadelphia hospitals was required.

The course was then three years in length, but as each course of lectures lasted only four months, it was expected that during the remaining portion of the first two years the student should receive private instruction.

As the period of the school term was so short, it is interesting to note at what time of the year the various courses of lectures began.

This, it will be seen, varied greatly according to the geographical position of the institution. At Dartmouth and the University of Vermont the term began in August. In Bowdoin College, Maine, however, it began in the middle of July, continuing until the middle of May, that is, the term time in the far north was in the summer or spring.

At Yale and Harvard and in Philadelphia and New York the term opened at the end of October or the beginning of November, as did also the schools in North Carolina and Kentucky. The University of Virginia, with its long course of ten months, began September 10th.[4]

Although the term time was exceedingly short in some schools a large amount of work was crowded into the daily routine of the students. Five or six systematic lectures a day, with attendance on clinics and dissections when possible, was considered nothing more than a fair amount of work for the medical student to digest properly.

This system of teaching remained practically unaltered in 1851, if we may judge from a report to the Committee on Medical Education of the American Medical Association.[4] In regard to the private instruction which was supposed to continue during the remaining eight months of the year, the report states that a very large proportion of students simply read medicine under the direction of their preceptors. Anything like careful instruction upon the part of the teachers did not exist. The student neither while attending lectures nor while in his preceptor's office was encouraged in anything like faithful and rigid study. To remedy the defect, private schools for teaching medicine were founded by enterprising physicians and surgeons and these quiz classes which were then inaugurated, became a prominent feature of the national system of teaching. Many a distinguished professor has first won his spurs at these private schools, and many valuable experiments in medical education were carried on by these men. As the college term has lengthened, the necessity for these accessory courses has diminished, and in many cities the extra-mural instruction, whether by private school or by teacher, has passed into history. No one will, I presume, regret the departure of the year of private teaching, "by some respectable practitioner," whose certificate, purchased by a handsome fee, came eventually to have so little meaning. When this custom was first inaugurated it was the sole method of inspection, and during the long period of apprenticeship the student received a large amount of instruction of the most valuable sort. When the medical school came into existence the attempt was made to combine the two systems. The practitioner, relieved from the responsibilities of giving a complete course of study to the student, gradually relaxed his efforts as a teacher until this part of his daily work came to have only a nominal value.

According to Davis, it consisted in 1877 in little more than the registry of the student's name in the doctor's office, permission to read the books of his library or not, as he chose, and the giving of a certificate of time of study for the student to take to the medical college where he expected to graduate.

At the beginning of this century the successful practitioner gave a prominent place in his household to the medical student. I have often heard my father and many other practitioners of his day tell stories of the school life of those times. The office in the old homestead where I began the practice of medicine, then a luxurious library, was in those times a plain room with a sanded floor, occupied during the day by a small band of medical students who all boarded in the same house. The old room was the scene of many amusing stories of schoolboy life, and also of thrilling tales of escape, from the indignant pursuer, by the hero of some graveyard scrape which was rendered necessary by the peculiar laws of that period. This phase of student life has long since passed away and the equally agreeable and far more profitable

[4] W. Hooker, M.D., 1851.

experience of hospital life has taken its place. Would that I could add that such hospital experience was now the privilege of every medical student in the land.

As we approach the middle of the century, we find the nation growing rapidly in population and prosperity, and a corresponding increase in the numbers and activity of the medical profession. From 1830 to 1845 the number of medical schools in the United States had more than doubled.

At a meeting of the Medical Society of the State of New York in 1839, when the subject of medical education was brought forward, it was proposed to hold a national medical convention the following year in Philadelphia, consisting of representatives from the different schools and State societies. No response was made to the action of this society, but in 1844 Dr. N. S. Davis, then a delegate from Broome County, New York, offered a resolution that a national convention be called in 1846, and the American Medical Association thus sprang into existence, the fundamental idea, which brought about the formation of the Association, being the improvement of our system of medical education.

It was high time that some such movement should take place, as the rapid increase of the number of medical schools brought with it a constant increase in the laxity of methods of teaching.

The equipment of a new school was sometimes pathetic in its meagerness — a manikin and a few lecture rooms constituting the entire "plant" of the infant institution. It would not do to question the dean too curiously about the clinical facilities which the school enjoyed; and as for laboratory work there were few teachers sufficiently advanced in their ideas to think of criticising the absence of such instruction. There was, indeed, no time for it. Every available space in the tabular view was filled with lecture hours. Professors were asked to come from neighboring towns to assist in teaching, and often gave two lectures in the same day. This cramming process, which seems so peculiarly American in its hustling activity, is perpetuated to the present day in a limited number of schools, chiefly those situated far from medical centres. As Oliver Wendell Holmes has said, life at that time was cheap; medical visits in the country were worth only twenty-five cents apiece, and the ambitious student could not afford to make an expensive outlay for his future work.

The American Medical Association therefore justly put on record its opinion, "that the abuses which exist in the modes of medical education pursued in this country demand the serious consideration of the profession," and at each meeting it continued to sound a note of warning on this all-important subject.

One of the principal reforms which it proposed to bring about was the lengthening of the term of each year from four to six months, and you will doubtless be somewhat surprised to hear that at the second meeting of the Association, which was held in Boston, a paper was presented from the faculty of Harvard University opposing this proposition.

Tempora mutantur et nos mutamur in illis.

If Harvard was unwilling to lead in the matter of reform at that time, it is not surprising that the other schools should not have been persuaded to change their customs. To the Chicago Medical College — which was founded in 1859 — must be given the credit of having been the first to attempt to lengthen the college course and to establish the system of teaching upon the so-called graded plan.[5] The school was in fact organized for this express purpose.

Little change was, however, effected by the Association in the methods of teaching at that time, although the discussions which were constantly held were destined eventually to bring forth good fruit. During the following decade little was done in the way of reform.

Graduating from the academic department of Harvard in 1863, I had an opportunity to study personally the methods in vogue at that time and am the more competent to express an opinion as I passed one year of my course of study in Philadelphia. The old system of medical education was then in all its glory and presented a striking contrast to one who had been subjected for four years to the strict discipline of a well-conducted university.

The course of lectures in Philadelphia began about the first of November, and the day was occupied in a bewildering succession of lectures, on all of which the student felt called upon to attend, as he had been obliged to "take out tickets" for the full course. The teachers were able, conscientious, and in many cases brilliant men, and many a lesson then learned has been of value in after life. Clinical teaching was, however, largely crowded aside by the superabundance of systematic lectures. The course came to an end on the first of March, and the class — which was an enormous one — was allowed to scatter to the four quarters of the country. Many of my classmates returned the following autumn, and after attendance on a second course of lectures and having also handed in the certificate of study from the "respectable practitioner" were able to graduate in the following March; that is, after having been connected with the school less than eighteen months. This may appear to the younger members of this Section an absurdly short curriculum, but there was a considerable number of enterprising young men who did not propose to occupy so long a time in obtaining their education.

You will remember what has already been said about the period of the year occupied by the school term. At that time there were not only schools which had their college "year" in the winter, but there were spring "years" and summer "years" as well.

Several of my friends proposed accordingly, after leaving Philadelphia in March to take a spring "year" at another school, in accordance with a custom which many at that time followed. Such a student was therefore able on July 1st to show to the examining body, tickets for two full courses of lectures and a letter testifying to private instruction. It was notorious that many students at [illegible] were able to obtain a degree after nine months only of medical study. The custom of short courses of study at different periods of the year unfortunately still prevails. This zodiacal paradox has not yet been fully eliminated from the medical calendar. The condition of teaching at Harvard was practically the same as at Philadelphia.

It is not surprising that the best class of students were dissatisfied with the opportunities, and that the number of those who found it necessary to go to Europe to complete their education was constantly increasing. Two and even three years of study was not considered too long a time to occupy in this manner.

[5] N. S. Davis: Contributions to the History of Med. Ed., etc., 1877.

It is true that spring terms of a supplementary nature were organized by most schools, and those students who chose to remain could receive instruction throughout the year. The majority of students, however, disappeared, many of them employing their time in other occupations to earn sufficient money to pay for a second course of lectures. The class of individuals who studied medicine at that time seemed far inferior to the medical student of to-day in culture and refinement. President Eliot says of the medical students of that period: "In this university, until the reformation of the school in 1870–71, the medical students were noticeably inferior in bearing, manners and discipline to the students of the other departments; they are now (1888) indistinguishable from other students."

The date which I have just mentioned marks the era of a great change in the history of medical education. The rising generation of teachers were not content with the antiquated methods of a previous century; they had learned of a new order of things in the centres of medical learning in Europe. As the old generation of teachers went out and a new one came in, the modern ways of teaching grew into a substantial system which had come to stay. Harvard adopted the graded course of three years' study, but she did also far more than that — and in this respect she stands in advance of almost every other school in the country — she lengthened her course to nine months, so that her two terms correspond with those of the other departments of the university and represent a full year's work.

I will not undertake to record the history of the reform in medical education since that time; it is familiar to most of you. The example which has been set to the rest of the country by the University of Pennsylvania and by the College of Physicians and Surgeons of New York is too well known for me to repeat them here.

While criticising, as I have done, the work of a previous generation, I ought to remind you that our forefathers accomplished what they did only by individual efforts. There were no governments, and as a rule no liberal benefactors to back them in their undertakings. Their schools had to be conducted on business principles, with a keen eye to the practical success of their venture. During the past twenty years, it is true, a number of State universities have been established. In the University of Michigan, and possibly in one or two other State universities, the medical professorships like those of other departments, are sustained by the income from the general endowment, independent of fees derived from medical students; but, as a rule, the success of the schools has depended upon the patronage which it has received. It may be justly said, therefore, that the whole system of medical education in this country is the spontaneous outgrowth of the work of the medical profession, and that it is due to their public spirit and disinterestedness that so important a department in the educational development of a great nation has been brought to its present state of excellence.

The good work has, however, but just begun. The reform of medical education is still in its infancy. If we are to believe all the glowing announcements which we read in the annual catalogues of the various schools, we might be lulled into a sense of calm security for the future; but, unfortunately, the actual practice of many, I might say a majority, of the schools does not come up to the ideals which are here set forth.

The essential points in the new scheme of education have been well stated by our President, Dr. Pepper:[6]

(1) The establishment of a preparatory examination.

(2) The lengthening of the period of study to at least three full years.

(3) The careful grading of courses.

(4) The introduction of ample clinical and laboratory instruction.

(5) The establishment of fixed salaries for the teachers.

In a general way we may obtain some notion of the improvement which has been made by a study of the report of the Illinois State Board of Health for 1891. According to this report there are now 148 medical schools of all kinds in the United States and Canada. The number of those requiring certain educational qualifications for matriculation is 129.

The number of schools requiring attendance on three or more courses of lectures was, in 1882, twenty-two. In 1891 the number was eighty-five.

There has been also a gradual increase in the duration of the lecture terms from an average of 23.5 weeks in 1882–83 to 26.3 weeks in 1890–91. In 1882–83 there were eight colleges that had but sixteen weeks; the number of colleges having terms of six months or more is now 111. The number of colleges which have graduated students at the end of the second course of lectures the present year is less than 10 per cent. of the whole number of schools in the country.

There are now in the United States thirty-two examining and licensing bodies that do not give instruction. Although the work of these licensing boards is far from uniform, a great deal has been accomplished by them. There are at the present time fifteen States with Practice Acts that require an examination of all persons desiring to practice medicine in the respective commonwealths. These States include nearly 50 per cent. of the entire population. In many States the whole complexion of the medical practice has been changed by the clarifying influences of these bodies. The reports on medical education by the Illinois board, I do not hesitate to say, have exerted a more powerful influence on the movement in education than any other publication which our medical literature has produced.

The effects of these Medical Practice Acts which establish a minimum of time spent at medical lectures and provide an examination for those who wish to become practitioners, are shown in the statistics which have just been given. At the present time State examinations are required in Minnesota, North Dakota, Montana, Washington, North Carolina, Alabama, Florida, Virginia, New Jersey, New York, Nebraska, Maryland and Utah.[7]

Millard, who has had experience in framing the act of Minnesota, believes that it would be an improvement upon the Medical Practice Acts at present in existence, to separate the two functions of the board, the licensing power and the educational supervision.

[6] Introductory Address, Philadelphia, 1877.

[7] Millard: The Necessity and Best Methods of Regulating the Practice of Medicine. Journal Amer. Med. Ass'n., July 30, 1892.

He thinks that the best interests of the public will be observed by assigning the duties of the State licensing power to the various State Boards of Health. The regulation of all forms of education should, on the other hand, be vested in a central power consisting of a single board, to be known as a State Bureau of Education, with power to regulate all educational institutions granting degrees, together with the power of granting charters and revoking the same; particularly should this apply to all institutions wishing to afford the community any of the various forms of higher or special education.

Having thus sketched the progress of medical education up to the present time, let us now glance at some features of the present system in which it is desirable that further improvement should be made.

The importance of a preliminary training for the study of medicine is a problem which has occupied the attention of our most prominent teachers. That the medical student should have received a fair amount of education goes without saying. The importance of a proper preliminary education is thus forcibly stated by that most experienced of German teachers, Professor Billroth. He says in reply to the objection to a preliminary study of the natural sciences as a basis of a medical education:

"The educated of all nations should not fail to encourage to their utmost, knowledge and study — in all countries and stations of life they should not fail to maintain the standard which they have set up, both for themselves and others; they should not fail to support the government in all efforts directed towards this end.

"The physician, the lawyer, the school teacher and the clergyman form the nucleus of culture in the community; they are, especially in the country or small towns, the representatives of the educated element of society. The people seek their advice in time of need, and they are their sole source of knowledge in many things.

"To neglect the education of such persons, to lower their mental and scientific standard, to bring them up so that they know no better education than the tradesman, the tailor and the cobbler, would be, in my opinion, the suppression of the educational development of a nation and is a policy both corruptible and immoral in principle, as it would inevitably ruin a nation and bring it prematurely to that point of decadence where it would become the prey of others."

The importance of these views is fully appreciated in Germany, where the professional schools are integral parts of the university, and entrance to the professional schools depends upon the previous completion of the course in philosophy, a course which corresponds to that of our academic degree.

In Dr. Holmes' suggestive article[8] on this subject it is shown that while the increase in the total number of medical students has been very great during the last decade, the increase in the number of "college men" who have entered the profession has been very slight, and in some of the more prominent schools the percentage has even slightly diminished. The author says: "It cannot then be doubted that relatively a smaller number of medical students have a bachelor's degree than in 1880, though the education of the average medical student is superior to the average medical student ten years ago." Although the proportion of medical students to students of law and divinity is greater in the United States, the relative proportion has diminished in the last ten years, whereas in Germany in the same period, a period during which medicine has become more of a science and the domain of surgery has increased under antiseptic methods, the proportion of medical students to the students of other professions has greatly increased. The reason for this variation in the proportion of students in the two countries is explained by the imperfection of our system of education. Educators have not had proper control and medicine has not been placed upon that dignified scientific basis which it enjoys in Germany.

Dr. Holmes complains that the medical department is neglected by every university in the United States. "It is farmed out or left to shift for itself."

Harvard has recently made an attempt to overcome the difficulty by a modification of the academic course. As Welch points out in an article on this subject:[9] If a young man choose the medical profession he should devote at least four years to medical studies, including the preliminary sciences. If he supplements this year with a year in a hospital and a year or two in study abroad, and all this work has been preceded by a college academic course, he would not be able to enter upon the practice of his profession much before the age of thirty.

Dr. H. P. Bowditch,[10] dean of the Medical Faculty of Harvard, has strongly advocated a change which would overcome this difficulty. The average age of students who enter the Harvard academic department, as President Eliot has shown, has been gradually rising during the whole of this century until it has reached nearly nineteen years. The student who enters the medical school therefore finds himself just beginning the preparation of the real work of his life at an age when many of his contemporaries are already engaged in the productive work of their professions. In Germany the best class of students begin their professional studies at a little earlier age than that at which our young men enter Harvard College. As the course of study leading to the degree of doctor of medicine lasts five years, it follows that the German physician is ready to begin practice before he is 23½ years old.

The average age of matriculants at Oxford is 19 years, and it is perfectly possible for an Oxford student desiring to study medicine to begin his purely professional studies before the end of his second year of college life. The dean writes me upon this subject as follows:

"There are many students in our school who have had one or two years of college life either as special or regular students, and these have entered the medical school because they have felt the necessity of getting started in their life work. These men would have been glad to take the A.B. degree if it could have been procured in a shorter time, but they consider it too dearly purchased when it involves so much delay in beginning their professional life."

It seemed, therefore, reasonable to the Medical Faculty of Harvard to make the following proposition, namely, that the academic council should consider the expediency of granting the degree of A.B. to all undergraduates who should subsequently take the longest course of study offered at the professional school after three years' attendance in the academic department — the professional degree and that of A.B. to

[8] The Forthcoming Report of the Bureau of Education on Professional Education in the United States, Jour. Amer. Med. Ass'n., January 14, 1893.

[9] Some of the Advantages of the Union of Medical School and University. 1888.

[10] Remarks made at a meeting of the Academic Council, 1887.

be given simultaneously at the end of the professional course. One of the medical studies at least can be obtained in the usual college curriculum, and general chemistry is frequently "anticipated" by students who enter the medical school. It is hoped, indeed, that this course will soon become one of the "preliminary studies" to medicine. It would be a short step to place one or two more of the scientific medical studies on the list of academic electives, and a whole year could be thus anticipated. The relations of professional schools to the university are not appreciated in the same light that they are in Germany, and the proposition of the medical faculty after much discussion was finally declined. The advantages of a more intimate relation between the medical school and the university are clearly set forth by Welch in the article referred to. The duplication of laboratories is thus avoided, and men of different branches of science are brought more intimately together. The important departments of botany, zoölogy, and comparative anatomy cannot fail to have an elevating influence upon the work done in a medical school. How much more rapidly might not original investigation progress when different branches of science work in a common cause. It is here that the great strength of German science and progress takes its origin.

A movement in the same direction is the establishment in our colleges and scientific schools of courses of tuition, intended specially for the benefit of those who intend ultimately to study medicine. Such a course has been planned by Professor Shaler in the Scientific School of Harvard, and a similar course is offered by the Institute of Technology.

Professor Shaler's course preparatory to medicine consists of two years. In the first year we find physics, zoölogy, botany, general chemistry, rhetoric and elementary French or German, and freehand drawing among the studies required.

In the second year there is botany, zoölogy, comparative anatomy, geology, comparative osteology, physics, qualitative analysis and themes.

It is certainly to be hoped that the medical teachers of the United States will not remain content with the very elementary examinations which are now demanded for those students who have not received a college education.

The advantage of a previous college training is shown in some statistics given by Billings [11] of examinations conducted by the examining boards of the army and navy. Of those candidates who had a college degree 34 per cent. were successful, and of those who had no such degree 28.9 per cent. succeeded. It is interesting in this connection to note that taking the medical schools of Harvard, Yale, the College of Physicians and Bellevue Hospital of New York, the University of Pennsylvania, and the University of Virginia together, 46.1 per cent. succeeded, while for all the rest of the schools in a body, 22.3 per cent. succeeded.

One of the most prominent features of the new education is the character and amount of laboratory work which is now required by our medical school. The new building of the Harvard Medical School, erected twelve years ago, showed the importance which its faculty attached to this means of teaching the student. Already the large addition of the Sears' laboratory has more than doubled the facilities of this department of the school. The University of Pennsylvania has felt the necessity of increasing the facilities of laboratory work and has received a munificent endowment for its department of hygiene. The literature of this part of our educational system is already becoming voluminous. The recent reports of Vaughan and Holmes in behalf of the work done at the University of Michigan and of the College of Physicians and Surgeons of Chicago, respectively, show the interest which is taken in this subject in some of the western schools.

General chemistry forms so large a part of the first year's work in the Harvard Medical School that it is proposed to make room for other valuable work by making this study one of the requirements of admission. This course is already anticipated by most of the college graduates. The course on embryology and histology is at present a required one, and lasts throughout the year. Students are obliged to keep books in which drawings are made of the specimens studied, and these books are examined by the teacher. Those who do not possess microscopes are provided with them by the school, and the equipment of this department enables it to handle classes of 150 students. Professor Minot, who conducts this course, urges the addition of a course on biology to the work of the first year, as it would not only enable the student to pursue many of his studies more intelligently, but would add greatly to the value of all original work done by the student or physician.

The new four years' course has been so arranged that the technique of bacteriology comes in the first year. This is a time when the student has more time for laboratory work, and it paves the way for special work in the study of these organisms in connection with pathology, which is placed in the second year. I shall leave a more detailed statement to Professor Ernst, who will have something to say upon this subject later. Bacteriology needs no special plea to-day. It cannot even be regarded as a purely scientific study. No practitioner of medicine or surgery who emerges from one of our schools to-day should be considered properly equipped for his work unless he has been trained in such a laboratory. No physician can expect to unravel the secrets of disease without a practical knowledge of the demonstration of certain forms of bacteria, and there is certainly no better school for aseptic surgery than the bacteriological laboratory.

The study of pathology at the Harvard Medical School [12] is conducted by Professor Councilman, not only by lectures, but by demonstrations, recitations and exercises in pathological histology. The latter course, which has hitherto been optional, is now obligatory. The relation of bacteria to disease is taught by the study of certain types of disease, as tuberculosis, suppuration, pneumonia, etc.

Demonstrations are given twice a week of material obtained from the hospitals and private practitioners. This is a laboratory exercise. Individual members of the class are called upon to study the specimens. They then carry them around to the other members of the class, and demonstrate and explain to them the lesions. Each student in this way has the specimen demonstrated to him. In the course on pathological histology the student is required to make drawings of the sections studied.

An opportunity is given to a certain number of men, who have gone through with their course in

[11] Ideals of Medical Education, 1891.

[12] Bulletin of the Harvard Medical School Association, No. 4.

pathology to act as demonstrators the following year and to assist in teaching. Places are assigned in the pathological laboratory to a certain number of students who have done well in their studies, and opportunity is given them for special study or original investigation.

A type of laboratory course, which I think is peculiar to Harvard, is that on the application of bandages and surgical apparatus. It is a purely laboratory course, is given to students at the beginning of their second year and is confined to a detailed study and drill in the practical part of such work. Bandaging is taught upon the living subject and upon wooden models. The feature of this course which is perhaps most valuable is the preparation and application of all the forms of stiff bandages. In this way every member of the class learns thoroughly the elementary part of this work before he begins to practise upon patients in the hospital, and no student leaves the school without becoming an adept in the application of the stiff bandage.

Another subject which is receiving more and more attention yearly is that of clinical instruction. The weakness of this feature of medical education was one of the glaring faults of the old system, and arose out of the fact that hospitals were far less numerous than they are at the present time, and that, from the necessities of the situation, the independent origin of the medical school became a custom which has continued almost unimpaired to the present day.

In Boston the medical school flourished for nearly one-third of a century before its teachers realized the importance of this problem. A circular was then issued in 1810, in which the statement was made that "a hospital was an institution absolutely essential to a medical school." Would that all teachers of that time had realized sufficiently that fact and had educated the public to recognize the necessity of such a close relation of the two. Many of the older members of this Congress can remember the old-fashioned prejudice which resented the intrusion of students into the hospital wards. The theory of the trustee of that time was: This money was given for the cure of patients and not for the education of physicians. They could not be persuaded that the two interests were identical.

The change of feeling in more enlightened times was indicated by the benefactor of the great Johns Hopkins Hospital. At the opening of that hospital in 1889, Dr. Billings showed the advantage of such a union in the following words:

"It is well known to those familiar with the subject that the sick in a hospital where medical instruction is given receive more constant, careful and thoughtful attention than do those in a hospital where no such instruction is given. The clinical teacher must do his best; keen eyes will note every error in diagnosis, every failure in results of treatment. Moreover, the very act of teaching clarifies and crystalizes his own knowledge in attempting to explain, the dark places become prominent and demand investigation, and hence it is that those cases which are lectured on receive the best treatment. I need say nothing here on the other side of the question; the value of properly trained physicians to the community and the necessity for hospital instruction in such training. Johns Hopkins understood all this, and especially directed that 'in all your arrangements in relation to this hospital you will bear constantly in view that it is my wish and purpose that the institution shall ultimately form a part of the medical school of the University.'"

The reaction in favor of clinical teaching is becoming daily stronger, and no school can hope to compete with the great schools of the country which does not have control of what is usually called "clinical facilities." This term must unfortunately still be used; for the number of schools which have a hospital of their own is yet exceedingly small. The union between the two is in most of our large cities becoming a more and more intimate one.

Another immense advantage which the possession of a hospital gives to a faculty is the control of appointments. Most schools are now obliged to select their teachers from members of the staffs of hospitals in their city who have services at times of the year which enable them to teach. These individuals are appointed by laymen who have no knowledge of or regard for the necessities of medical education. Faculties thus placed are unable to select teachers of national reputation, as there is no appointing power which enables them to give such a person the material with which to teach. This is a grave defect in our system, and one which the leaders in medical education should not forget to impress upon the profession and the public.

But, while applauding the movement in favor of clinical teaching, it is perhaps well at the present time to consider whether systematic or, as it is usually inaccurately called, "didactic" teaching should be abandoned. The discussion as carried on in medical journals, appears to lean in this direction. A course of systematic lectures enables the teacher to cover ground which he would be unable to do, even in a clinic most richly endowed with material. The method of handling the subject differs entirely from that adopted at the bedside, and in a well regulated four years' course I believe the systematic lecture should still retain a prominent place. Clinical instruction should be abundant and of the most varied kind. Instruction of the class in small sections is a most desirable feature of this department. It involves a greater expenditure of time, an increase in the teaching staff and great ability as an organizer in the head of the department. It is the squad drill, however, which brings the student in most intimate contact with disease.

To carry out these ideals necessitates a "plant" far in advance of that which the average school now possesses. No such enterprise can be undertaken without that aid which has hitherto been conspicuous by its absence. I refer to endowments; the valuable paper of Dr. Bayard Holmes already referred to gives some interesting data on this subject. He says:

"The productive funds in the hands of medical schools, both those connected with and those independent of universities in the United States was in 1889, $249,200, while at the same time there was in the hands of schools of theology productive funds to the amount of $11,939,631. The value of buildings and grounds used by medical schools at the same time was $4,047,618, and the theological schools were accommodated with buildings and grounds valued at $7,762,095. The medical schools had in 1889, 12,238 students who paid tuitions to the amount of $763,761, while at the same time the theological schools enrolled 6,989 students.

"I am able to reinforce these figures by an abstract of the statistics for medicine, theology and technology as reported to the Bureau in June, 1892. The medical schools possessed buildings and grounds in 1882 valued at $7,507,937, and productive funds amounting to $611,214. Medi-

cal departments of State Universities also received State aid in 1892 amounting to $40,500, which, if capitalized at 5 per cent., would be equal to an endowment of $810,000; making a total endowment of $1,421,214. There were 16,731 medical students in attendance.

"The theological schools report productive funds amounting to $17,599,979, and stated, at the same time, the value of their buildings and grounds was $10,720,860. They had 7,672 students in attendance.

"Technological schools report productive funds amounting to $13,229,940. These institutions received from State appropriations or municipal aid in 1891-92, $747,504, which, if capitalized at 5 per cent., would be equivalent to an endowment of $14,950,080; making a total endowment for schools of technology of $28,180,020. There were enrolled in the schools of technology 10,921 students, about one-third of whom were in preparatory courses. It will thus be seen that the endowment of theology is increasing at the rate of about two million dollars a year. The technological schools are well provided for, but medicine has scarcely raised its endowment, even at the most liberal estimate, to a million and a half."

Probably the available funds possessed by our medical schools are somewhat larger than these statistics show, but they give the proportions which are needed to impress upon us how little financial encouragment medicine receives. When we realize what a valuable factor the medical man is in the rapidly increasing development of the territory of a vast and prosperous country like ours, it seems as if his claims to receive encouragement should be listened to. He does not build railroads or organize society in new lands, but he is in the foremost rank of pioneers, with the complete equipment which our teachers can give him today, and he becomes a most valuable member of society. He protects the young colony from epidemics; without him State medicine could not exist, and States could not be provided on a basis which would ensure prosperity.

These ideas should be impressed upon our men of wealth and upon the State governments as well. In the meantime it is important that we should adopt as a principle in our new departure in education that the medical faculty should have personal control of hospital wards and management. Let this work begin in a small way at first, but with a view to future development. Such a change can only be brought about by a slow process of evolution. The sooner, therefore, the principle is recognized and adopted, the better. It is difficult for a prosperous school which has abundant opportunities for bedside teaching to realize this, but it cannot develop beyond a certain point until it has established its own independence.

I cannot help believing that in this direction lies one of the greatest avenues of development of our system of medical education in the future.

THE MISUSE OF DRUGS IN MODERN PRACTICE.[1]

BY JOHN T. G. NICHOLS, M.D., OF CAMBRIDGE.

(Concluded from No. 11, p. 264.)

LET us now turn to the brighter side of our subject, and consider some of the great advances in the art of healing in which drugs have had no part. The work which State medicine has done was ably presented to this Society four years ago, by one who has won an enviable distinction in this department. I shall draw my illustrations from those things that come home to us in our daily work.

The advance in knowledge that has come from modern discoveries in Biology has revolutionized the art of medicine in many of its aspects. The antiseptic method has so changed the practice of surgery and of midwifery, that some most fatal diseases, which to those of us now only in middle life, were frequent reminders of the limitations of our art, are almost unknown to the younger members of this Society.

Let us carry ourselves back in memory to the operating-room of the Massachusetts General Hospital thirty years ago. It was, I suppose, as complete in its appointments as that of any hospital of the time. Its surgeons were certainly the equals in knowledge and skill of those of any institution of its kind. Taking off their coats, from motives of economy, certainly not of cleanliness, the surgeons put on the garments reserved for their work, which had hung in a dark closet since they were last used. Stained and stiff with the blood of scores of patients, they were worn, perhaps, with something of the pride which a veteran soldier feels in the uniform that bears the marks of many a hard fought field. Instruments were taken from the cases, and used without further preparation. Sponges were washed in plain water, and used from case to case. Hands were washed in soap and water only. The patients were removed to the wards, to be a source of anxiety to their attendants until their wounds were healed. That this anxiety was justified the records of the hospital will amply prove. One of those surgeons in the annual address to this Society twenty-nine years ago, thus describes what happened after operations: "I remember the time, when after an amputation, or the excision of the breast, or a large tumor, it was the universal rule to bring the edges of the cut integuments together nicely with straps, compresses, and a bandage, with the full assurance of finding the wound nearly healed on the removal of the dressings. At the present day, however, such a result is rarely attained in city practice; union by first intention being, for the past twenty years, the rare exception."[24]

I need not draw the picture of the operating-room in the same hospital to-day. You are all familiar with it. The son of the man who wrote the words I have just quoted would tell you that the exception in 1864 has become the rule in 1893.

The use of dangerous drugs as disinfectants, and in protective dressings, was considered a necessary part of antiseptic treatment in its early days. Great harm, and even death resulted from their use in no inconsiderable number of cases. Now antisepsis has given place to asepsis. Heat has largely supplanted poisonous drugs, and the treatment of wounds has become much simpler and safer, and has lost nothing in efficiency. I will not weary you with illustrations of cases to which the surgeon of to day brings healing, where the physician of thirty years ago stood helpless, happy if he could give his patient an easy death.

The statistics of lying-in hospitals since the importance of cleanliness in midwifery practice was accepted by the profession, show how great a saving of life has resulted from the discovery of this truth, which was made and announced by Semmelweis, in 1846.[25] In the wards of the Vienna hospital in which students

[1] The Annual Discourse delivered before the Massachusetts Medical Society, June 14, 1893.

[24] Recent Progress in Surgery, by J. Mason Warren, M.D., Medical Communications of the Massachusetts Medical Society, vol. x, No. iv, Boston, 1864.

[25] London Lancet, October 29, 1892.

had their clinical teaching in midwifery, the mortality averaged nearly ten per cent., while in those to which only midwives had access, it was less than four per cent. Semmelweis connected this difference in mortality with the fact that the students handled dead bodies, while the midwives did not. The discovery was made, the remedy was applied. The students were directed to wash their hands in chlorinated water before entering the lying-in wards. The mortality fell from over twelve per cent. to less than four per cent. in six months, and later, to less than two per cent. The principle of aseptic midwifery was found out. Its only advance has been in its details. Chlorine still maintains a high rank in the list of modern germicides. The profession was so blinded by theory that these facts, so plain that we wonder they were not at once accepted, were lost sight of. The literature of puerperal fever grew. The treatment by drugs was always ineffective, while the real cause was lost sight of in the many theories of its nature with which the books abounded. Semmelweis died before the truth of his discovery was recognized. Now it is proposed to build a monument to his memory as the founder of aseptic midwifery.

While we accord all honor to the man who found out the cause of puerperal septicæmia, and told us how to prevent it, we should not forget that an honored member of this Society first brought before the profession facts which should have opened its eyes to the truth. More fortunate than Semmelweis, he lives to see the correctness of his views acknowledged by all. In 1843, Oliver Wendell Holmes published his essay entitled "Puerperal Fever a Private Pestilence," in which he cited many cases showing that this disease had often followed the path of individuals, while their neighbors did not meet with it. He stated its infectious nature. He declared that a physician should cease to attend cases of labor if puerperal fever occurred in his practice; that he should not go from an autopsy to the lying-in chamber; and that he should keep himself scrupulously clean in his dress and person. These views were violently opposed by some, doubted by most, acted upon by a few. To show how theory sometimes treats facts when they happen to oppose it, I quote from the essay the words of Professor Hodge of Philadelphia: "The result of the whole discussion, will, I trust, serve not only to exalt your views of the value and dignity of our profession, but to divest your minds of the overpowering dread that you can ever become, especially to women under the extremely interesting circumstances of gestation and parturition, the minister of evil; that you can ever convey, in any possible manner, a horrible virus, so destructive in its effects, and so mysterious in its operations, as that attributed to puerperal fever." [26]

Let us narrow the illustration to a single disease. Not many in this audience can go back in memory to the time when croup was supposed to be a single disease. The sudden and noisy attack which strikes terror to the mother's heart, and summons the tired doctor from his first sleep, was looked upon as the early stage of what we know as membranous croup. All cases were subjected to the same treatment. Bleeding, mercury, antimony, were freely used. Hive syrup was a domestic remedy, which still survives in the Pharmacopœia under the name of Compound Syrup of Squill. If the patient lived, drugs got the credit. If he died, friends were comforted by the assurance that nothing had been left undone. That it would have been well if much had been left undone, no one who has seen a child in the collapse of antimonial poisoning will question.

More than fifty years ago, John Ware published his investigations on the natural history of croup. He showed that at least four diseases had been included under this name. One was so insidious in its onset that it seldom came under the notice of the physician until it was well advanced. Its diagnosis was not difficult. In almost all cases it could be determined by the presence of exudation in the throat. It was very fatal, and the treatment then in vogue certainly did no good, and probably did harm. A second form resembled the first in the character of the voice and respiration, but was distinguished from it by the absence of false membrane, and its almost certain recovery. The other forms, alarming in their early symptoms, had no exudation in the throat, and got well under simple treatment.[27] Time has confirmed these results, and bleeding, mercury, and antimony are things of the past in the treatment of croup.

Time will not allow me to pursue this subject further. The gain which our art has made from increased knowledge of the natural history of disease, cannot be overestimated. It has overthrown false and harmful methods of treatment, not by substituting others equally erroneous, but by leading us on to the solid ground of truth.

I have brought to your attention some of the ways in which, as I believe, we fail to uphold in the community correct ideas of the powers and limitations of the medical art. I have tried to set forth some of the limitations to the usefulness of drugs, and to point out the great advances which have followed a better knowledge of the natural history of disease. Let me not be understood as denying the good which drugs may do as aids to nature. The practice of our art would be dreary indeed were we wholly deprived of them. But that the great activity of the chemist and the pharmaceutist in these days is leading us away from the right path, I am convinced. The history of medicine is full of illustrations to confirm me in this belief.

It needs no argument to prove that the public does not judge our art correctly. Nor is it true to say that ignorance is the only cause of this false judgment. The public is neither ignorant nor unintelligent in most matters affecting its welfare. It is well to ask if we are not responsible, in some degree, for a state of things which we cannot fail to recognize. These words of John Bell may have an application to the present day: "I have also observed, that where there exist any very singular prejudices connected with our profession, they have first arisen among the profession, though now, perhaps, they are to be found only among the vulgar; and when there have been ill-reports among the vulgar concerning the practices of medical men, they are seldom entirely void of truth." [28]

What, then, can we do to correct the false views of the powers and limitations of the medical art which still prevail?

We should teach that disease is not caused by the laws of nature, any more than the injury that the

[27] Contributions to the History, Diagnosis, and Treatment of Croup, by John Ware, M.D., Boston, 1850.

[28] The Principles of Surgery, by John Bell, London, 1826, vol. i, p. 16.

artisan sustains from the breaking of a scaffold is caused by the law of gravitation. The law is beneficent; the harm comes from violating it. If we could live in perfect harmony with the laws of nature, it is not unreasonable to say that disease would be unknown, and the end of life as natural and as painless as its beginning. This ideal condition can never, perhaps, be reached, but just as far as we have made progress towards it, has disease grown less. We have not, and never shall have the power to change the laws of health, but we can increase our knowledge of them, and declare the absolute dependence of our art upon them.

Sure as is the penalty of the violation of nature's laws, there is one upon which our art securely stands. It is well stated by one of our great surgeons in these words: "After a part has been changed by disease, it tends naturally to regain a perfect state." [29] Certain in its action as is this law, plainly as its working may be seen in disease, it is not fully appreciated, even in the profession. It is not strange that the public should have incorrect views of it. Recounting the advances of modern surgery, a recent writer [30] speaks of the old practice of leaving ruptures of the abdominal viscera to the unaided efforts of nature, and contrasts it with the resources of modern surgery, quoting Billroth as saying that the *vis medicatrix naturæ* is a better physician than surgeon. With equal reason might we blame nature if she failed to cure a case of pneumonia left uncared for in the street. Nature, not the surgeon, heals the wound. The old surgeon could cut as skilfully and sew as deftly as the surgeon of to-day. Ignorance of nature's laws tied the hands of the older man; a better knowledge of them enables the modern surgeon to remove the obstacles from her path.

From the standpoint of the physician, the argument still holds good. Experience proves how little we can control disease by drugs. The results of modern study point out clearly the way by which we may hope to prevent it, or to aid nature in her attempts to cure it.

We believe we have discovered in a bacillus the cause of consumption. If the seed falls into good ground it brings forth fruit. If it falls upon stony ground it withers away. How hopeless a task it is to utterly destroy the seed, a glance at a microscopic slide of tubercular sputum will convince us. How to make the soil infertile is the problem we have to solve.

If the seed falls into good ground, and brings forth an hundred fold, we still can see the working of the healing power of nature. She tries to wall off the diseased from the healthy parts. She throws off the tissues which the disease has killed. She closes the vessels which the process of destruction threatens to lay open. She tries to close the gap which is left, and she does not cease her efforts while life remains. Sometimes she succeeds in arresting the disease, and a study of these fortunate cases indicates the way our attempts to aid her should follow. The most sanguine believer in drugs will find little in this study to strengthen his faith. Pure air, good food, all things included under the name of hygiene, are the only agents in which we can put our trust.

The Cambridge Hospital has wisely chosen for the motto on its seal, these words, — "Man tends, God mends." The truth they express will only be made clearer as science advances towards perfect knowledge.

The wise general never fights on the ground his enemy has chosen, if he can avoid it. The quack takes his stand on the power of drugs to cure disease. Here he is strong. He can use the argument of *post hoc, ergo propter hoc*, more effectively than the educated physician. Restrained by no considerations of truth or humanity, his promises of cure are marred by no ifs and buts. We cannot wonder that the public, comparing his ways with ours, and finding the points of likeness I have described, should so often choose the broad way he offers, rather than the narrow way which rational medicine indicates as the only path to health.

Every man, says Bacon, owes a debt to his profession. It is given to few to be the discoverers of great truths, but the humblest of us may do his part to raise our art to a higher level. Let us give to drugs their proper subordinate place, using only those which experience has proved to be safe. Let us do all that in us lies to aid nature in her work. Slow to accept praise for our successes, let us study our failures with candid minds, and report them honestly, that others may learn from them. So shall we lend our influence to uphold in the community correct views of the powers and limitations of medical science and art, and to make clear the distinction between the regular practice of medicine, and the practice of quackery.

In thus discharging the debt due our profession, we shall best fulfil the duty we owe our patients. The relation of the physician to his patient is a sacred one. The sick man puts his life in our hands. He follows our directions without question. We have no more right to experiment upon him with a doubtful drug, without his knowledge, than the surgeon has to perform an operation without his consent. The law protects him from the operation he does not consent to; the moral law alone guards him from the drug which may be more dangerous than the surgeon's knife. "The first great law in therapeutics is to do no hurt."

And, finally, to use the words of Jacob Bigelow, "the importance and usefulness of the medical profession, instead of being diminished, will always be elevated, exactly in proportion as it understands itself, weighs justly its own powers, and professes simply what it can accomplish. It is no derogation from the importance of our art that we cannot always control the events of life and death, or even of health and sickness. The incompetency which we feel in this respect, is shared by almost every man upon whom the great responsibilities of society are devolved. The statesman cannot control the destinies of nations, nor the military commander the event of battles. The most eloquent pleader may fail to convince the judgment of his hearers, and the most skilful pilot may not be able to weather the storm. Yet it is not the less necessary that responsible men should study, deeply and understandingly, the science of their respective vocations. It is not the less important for the sake of those whose safety is, and always will be, committed to their charge, that they should look with unbiassed judgment upon the necessary result of inevitable causes. And while an earnest and inquiring solicitude should always be kept alive in regard to the improvement of professional knowledge, it should never be forgotten that knowledge has for its only just and lasting foundation, a rigid, impartial and inflexible requisition of the truth." Original Articles.

TYPHOID FEVER IN BOSTON.[1]

BY J. H. MCCOLLOM, M.D.

ALTHOUGH typhoid fever is not so prevalent in Boston as some of the other zymotic diseases, yet it is sufficiently frequent to demand a careful inquiry into the cause of its comparative prevalence. The influence of typhoid fever on the death-rate of Boston can be appreciated from a study of Chart A, which shows the number of deaths from twenty-five principal causes for the year 1892. The diseases generally classed among the zymotic are indicated by the broken line. From this comparative statement it is evident that typhoid fever is not a very potent factor in increasing the death-rate of Boston.

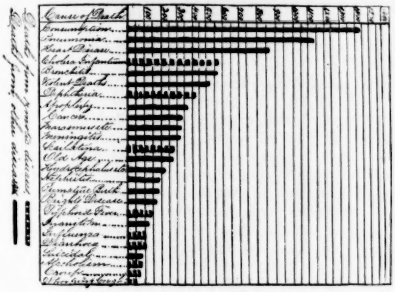

CHART A.

The effect of a good public water-supply in diminishing the prevalence of the disease is illustrated by the history of typhoid fever in this city for the past forty-seven years. A study of mortuary statistics shows that for the four years from 1846 to 1849 inclusive, when the water-supply was taken from wells the ratio of deaths per 10,000 of the living was 17.4; that after the introduction of Cochituate water in the latter part of 1848, the rate commenced to decline, so that in the semi-decade from 1850 to 1854 the ratio was 8.2 per 10,000 of the living. Since 1854, with a few exceptions, the rate has gradually diminished each year until it has fallen to 2.9, the rate in 1892. Another very interesting fact bearing on the subject of a public water-supply as compared with wells, is that in Charlestown, for the five years subsequent to the introduction of the Mystic water, 1866 to 1870, there was a very decided diminution in the ratio of deaths from this disease as compared with the five years previous to its introduction.

For the purpose of a study of the prevalence of typhoid fever in Boston as compared with the disease in ten American and six foreign cities Chart B, which shows the ratio of deaths from typhoid fever per 10,000 of the living in Boston, New York, Philadelphia, Chicago, a group of cities comprising Worcester, Lowell, Fall River, Cambridge, Lynn, Springfield and Haverhill, the aggregate population of which equals that of Boston, London, Paris, Berlin, Vienna, Glasgow and Moscow for the five years from 1888 to 1892 inclusive, has been prepared. It will be seen from this chart that the ratio of deaths per 10,000 in Boston is 3.64; that in New York the rate is slightly lower, 2.30; that in Philadelphia the rate increases to 6.49; that in Chicago the rate is 8.64; and that in the group of cities the rate is 5.11. So far as the foreign cities are concerned, it will be seen that Vienna, Berlin, London and Glasgow have respectively

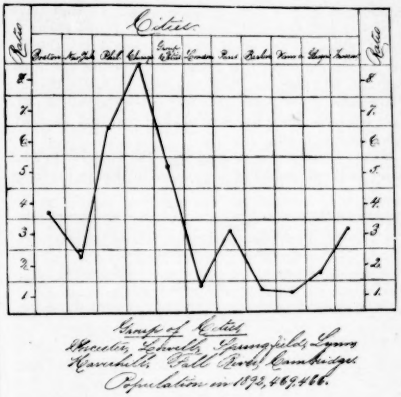

CHART B.

rates of 1.19, 1.24, 1.35 and 1.72; that Paris and Moscow have each a rate of 3.16, nearly the same as that of Boston. It should be remarked, however, that, owing to the prevalence of typhus fever in Moscow, the liability of mistaking typhoid fever for this disease is much greater than in any of the other cities, and therefore the statistics in Moscow cannot be considered absolutely reliable as far as typhoid fever is concerned. It is also evident, from a study of this chart, that in the

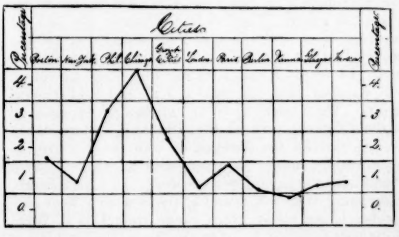

CHART C.

American cities, those having a good water-supply have a low rate, for instance, New York and Boston; that in Philadelphia and Chicago, the water-supplies of which are certainly not above reproach, the rates are comparatively high. In the group of cities it will be seen that the rate is nearly double that of Boston. While it is true that some of the cities, included in the group, have a good water-supply, it is also true that in all of them there are a greater or less number of wells which are likely to become contaminated by the

[1] Read before the Boston Society for Medical Improvement, May 8, 1893.

discharges from typhoid fever patients, and thus prove active agents in spreading the disease.

In order to avoid all sources of error in regard to the population which in some instances has been estimated and in some instances enumerated, Chart C, which shows the percentage of deaths from typhoid fever to the total mortality in these several cities, has been drawn. From this chart it will be seen that the percentage of deaths from this disease to the total mortality in Boston is 1.53; that in New York the percentage is .91; that Philadelphia and Chicago have a rate of 3.13 and 4.51, respectively. In the group of seven cities before mentioned the per cent. is 2.28. In the foreign cities it is found that London has a per cent. of .68; that in Paris the rate is 1.40; that in Berlin the rate is 1.58; that in Vienna the rate is .40; that Glasgow has a per cent of .77; and that in Moscow the rate is .83.

Chart D shows the ratio of reported cases of typhoid fever to the thousand of population in Boston for three

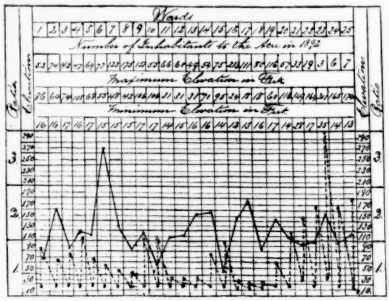

CHART D.
